$$a_{ij} = \begin{cases} f_j & \text{for } i = 1 \\ p_j & \text{for } i = 1 \\ 0 & \text{otherwise} \end{cases}$$

where f_j and p_j are the age specific fecundity and natural survival. The diagonal matrix \mathbf{D} with elements θ_i is the proportion of the i th age class surviving exploitation. The model has the merit of being conceptually simple and intelligible to non-mathematical biologists, although accurate field measurement of the necessary age specific parameters may present difficulties. Beddington⁷⁸ has, however, obtained reasonable estimates for red deer populations in Scotland. The harvest at equilibrium is given by

$$q = \sum_i (1 - \theta_i) n_i \quad (10)$$

and this is inserted in a Cobb–Douglas production function for the yearly crop

$$P = q X_3 = \beta X_1^{r_1} X_2^{r_2} X_3^{r_3} \quad (11)$$

where the X s are the number of stalkers, the area of the estate and the deer population respectively. Given the pattern of deer forest ownership in Scotland the estate size is not easily adjusted but the model can be used to provide a guide to the most profitable labour input.

Models such as the Beverton and Holt and Leslie matrix together with a variety of simulation models developed in the last few years provide the beginnings of tactical harvesting models, but there are many formidable problems to be overcome. In particular there are practical and theoretical difficulties in obtaining dynamic optimisation solutions to age structure models. These problems will be compounded when attempts are made to produce tactical versions from the few existing policy orientated models for multispecies harvesting and when, eventually, harvesting models encompass the whole ecosystem^{78,79}.

Fig. 5 Appropriate control strategies for pests categorised in terms of the r - K continuum⁸⁸.

Pest control

A further critical problem facing fishery ecologists is that of estimating parameters, in particular for density dependent processes^{61,80}. The theoretical consequences of different functional forms of these processes have been understood for some time but there are very considerable difficulties in obtaining accurate data. Insect populations, by contrast, can be more easily observed and experimented upon, so that considerably more is known about their population dynamics. This is particularly true of the relationships between insects and their predators and parasites, for which there is a range of mathematical models that have been well tested against laboratory and, less well tested against field data⁸¹⁻⁸⁵.

Surprisingly, however, there has been little effort to use these models to formulate strategies for pest control. A notable exception is Hassell and May's⁸⁶ analyses of the characteristics of insect parasitoids as agents of biological control. In a model which explicitly deals with spatial heterogeneity, population change for the host pests (X) and the parasitoids (P) is given by

$$X_{t+1} = \lambda X_t \sum_{i=1}^n [\alpha_i \exp(-a(c\alpha_i^\mu P_t)^{1-m})] \quad (12)$$

and

$$P_{t+1} = X_t - X_{t+1}/\lambda \quad (13)$$

where λ is the net rate of host increase, the $\{\alpha_i\}$ set defines the host distribution and μ , a and m are measures of aggregation, searching efficiency and mutual interference in the parasitoids. In general, high levels of a lead to low equilibria and high levels of m and μ to stability in the host population. Since highly specific parasitoids tend to show these features more markedly than polyphagous ones, it is argued that specific natural enemies are preferable as biological control agents where, for example in perennial orchards, equilibrium populations can be more readily maintained.

Recently, Conway⁸⁷ and Southwood⁸⁸ have attempted to provide a stronger link between theoretical ecological models and practical pest control, by applying the r - K selection continuum to the choice of control strategies. They distinguish at one extreme, r -pests such as the desert locust, characterised by high rates of dispersal and highly damaging population explosions, and at the other extreme K -pests such as the codling moth, with lower rates of increase, regulated by competition and whose status as pests is achieved more because of the character of the damage they cause. In between lies a large category of pests normally regulated at various levels by parasites and predators. Simple models^{89,90} have been produced for the different categories and used to prescribe general rules for control (Fig. 5). Although these notions are still somewhat crude and oversimplified they provide the beginnings of a fairly rigorous strategy analysis for pest control.

A good example of the intelligent application of simple models of this order is in pesticide resistance. Again, surprisingly, there have been no attempts until very recently⁹¹⁻⁹³ to model resistance in spite of its critical importance in modern pest control practice. Comins^{94,95} has, however, developed a deterministic Mendelian model which demonstrates, for example, the existence of a hysteresis effect in the presence of migration from untreated populations, the population jumping from high susceptibility to high resistance as migration drops below a critical level. Density dependence is included in the model in the form

$$X_{t+1} = \lambda X_t^{1-b} \quad (14)$$

where b is the density dependence coefficient. For perfect density dependence ($b = 1$) resistance time decreases with increasing kill but where the relationship is undercompensating ($0 < b < 1$) intermediate kills result in the fastest resistance. In general, for reasonable levels of density dependence it seems that resistance can be suppressed by using highly effective non-residual insecticides, strictly confined to the target population.

Simple density dependence models have also been used to explore the interrelationships between ecological and economic factors in pest control. In a study of the sugar cane froghopper, *Aeneolamia varia saccharina*, Conway *et al.*⁹⁶ show how the optimal spraying strategy is a function of the degree of density dependence between the different broods that the froghopper passes through in a season. In the absence of density dependence ($b = 0$) heavy spraying in the first brood is optimal but as the relationship goes from undercompensating to overcompensating ($1 < b < 2$) the spraying becomes progressively heavier in later broods. Models of this kind are not prescriptive but play an important part in determining which of a multitude of ecological factors merit further research before control decisions are made.

Dynamic programming⁹⁷ was used to arrive at the froghopper result and this technique has been used to derive optimal strategies for a number of pests^{91,92,98-101}. Its usefulness is restricted by the number of variables which can be included, but if this problem is resolved dynamic programming has a considerable potential as a tool for day-to-day management. As Shoemaker has shown⁹⁹ the results can be presented as simple decision rules in graphic form (Fig. 6), which allow an optimal strategy to be pursued even when the outcome of earlier decisions has not been as expected.

The problem of modelling age structure has also been tackled, as in harvesting models, by use of the Leslie matrix formulation^{96,102}. Recently Guttierrez, Wang *et al.*¹⁰³⁻¹⁰⁵ have used a continuous form, which is time and age dependent, to model both plant growth and the pest population on cotton and alfalfa. They seem to have been fairly successful in obtaining appropriate data but in general age class parameters are difficult to measure in many insect populations.

To date, most attempts at tactical models have taken the form of complex computer simulations. At worst they have suffered from the defects of the large-scale ecosystem models but there have been some notable exceptions, kept functional and useful because they have concentrated on the fairly circumscribed question of the optimal timing of pesticide application. Regev *et al.*⁹⁸ have developed such a model for the alfalfa weevil, *Hypera brun-*

Fig. 6 Optimal control strategies for the alfalfa weevil in terms of a standard insecticide spray (shaded area) and date of alfalfa harvesting¹⁰⁰.

Fig. 7 Path of a single outbreak cycle of the spruce budworm in terms of living foliage per branch and different densities of branches per acre¹¹⁰.

neipennis, and demonstrated that higher profit would accrue from earlier spraying in the season. Kiritani and his colleagues^{106–109} have similarly used a simulation model of the dynamics of the green leafhopper *Nephotettix cincticeps*, and the *Lycosa* spiders which are its principal enemies to demonstrate the detrimental effects of BHC spraying which leads to destruction of the spiders and resurgence of the leafhopper. As a consequence the insecticide has been phased out from control campaigns in Japan.

Perhaps the most successful simulation model has been developed by Holling and his co-workers¹¹⁰ for the spruce budworm (*Choristoneura fumiferana*) in New Brunswick. At first a very complex model, it has been progressively bounded so that the essential dynamics of the system (Fig. 7) can be represented in terms of a limited number of variables relating to the pest, its natural enemies, the three main tree species, weather and, significantly, space. The final model reproduces the budworm dynamics for a 17,000 square mile region in terms of 265 discrete subdivisions. The model has been used to derive strategies of control under a variety of objectives, one set of outputs being in the form of graphical decision rules (compare Fig. 6) for spraying and logging obtained by a Markovian optimisation procedure.

Decision making

Underlying most policy models is the assumption that the farmer or trawler owner is a profit maximiser and hence is risk neutral; that is he values each successive increment in income in the same way. In practice, however, resource managers, whether at the individual, corporate or national level, exhibit a wide range of attitudes toward the outcomes of their decisions. Norton^{111–113} has recently illustrated the problem in the context of pest control and demonstrated the value of Bayesian techniques in the relatively common situation where the farmer is risk averse; that is, he values initial increases in income far higher than later increases. For example Bayesian analysis of potato blight control in England with the objective of a long run average profit maximisation leads to schedule spraying in the Southwest and Fens and no spraying in the Southern and Northern Regions. Because of the high variance associated with no spraying, however, the risk averse farmer in the latter regions may decide to spray anyway. Bayesian analysis can be further usefully extended to assessments of the value of pest forecasting. It is often naively assumed that a forecast is always useful but in practice the value depends on critical threshold levels in the accuracy of the forecast.

Such decision making has eventually to be placed in the broader context of ecosystem and regional management, which is likely to have to resolve conflicting and often incommensurate objectives. The most promising of the multivariate decision techniques is multi-attribute utility analysis^{114,115}, which has the advantage of dealing with uncertainty in a rigorous manner and of directly involving the decision maker in the definition and weighting of objectives. In common with other techniques, however, it is essentially static in that it seeks to identify an optimal plan which is adhered to for the foreseeable future. But, experience shows that objectives change or hidden objectives become manifest and unsuspected and unforeseeable events arise to disturb the management plan. Walters¹¹⁶ argues that this problem is compounded by a tendency for a wrong policy or design decision to beget further wrong decisions when dramatic problems arise so that, in practice, there is a progressive foreclosure of options. These are issues which have been addressed in the spruce budworm¹¹⁰ and a related salmon study^{117–119}. A general conclusion is that the main goal of such studies and the models they generate is not to solve an economic maximisation function but to create some kind of robust system which is resilient to all conceivable ecological, economic, social and political change^{120,121}.

No unified theory

It is very clear from this review that mathematical modelling in the fields of vector borne disease, harvesting and pest control has proceeded at different rates and in largely different directions, despite Watt's vision of a unified science of resource management. Yet, it is also clear that each field could well profit from the experience of the others. Policy models, of the kind developed for fishery management are urgently required in both pest and vector borne disease control. Equally, the notions and models of density dependence that are being elaborated for pest control could provide a more powerful basis for determining strategies for harvesting and disease vector control. There is also a growing, albeit halting experience, in each field of attempts to incorporate the discrete variables of age, state and space in tactical models and to develop appropriately dynamic optimisation techniques, which needs to be shared. From this kind of cross fertilisation a common theory and practice of applied ecology could begin to emerge.

I thank D. J. Bradley, C. W. Clark, R. M. May and colleagues at Imperial College for helpful comments and criticism. Financial support from the Office of Resources and Environment in the Ford Foundation and the Natural Environment Research Council is gratefully acknowledged.

Ocean-floor magnetotelluric sounding over North Central Pacific

Jean H. Filloux

Scripps Institution of Oceanography, La Jolla, California, 92093

Observations on the sea floor of naturally occurring electromagnetic signals reveal information on the deep structure of the Earth. Recent magnetotelluric soundings on the North Central Pacific have produced conductivity measurements which may relate to the partially molten zone or asthenosphere on which the well lubricated oceanic plates slide.

OBSERVATIONS over a wide range of frequencies of slowly fluctuating natural electric and magnetic fields at the Earth's surface can be used to infer the distribution of electrical conductivity in the Earth's crust and mantle^{1,2}. Because of the

strong dependence of the electrical conductivity of terrestrial materials on temperature and composition³ the magnetotelluric (MT) technique is now accepted as a valid and attractive method of geophysical investigation on land⁴⁻⁸. Providing that electric and magnetic fluctuating fields can be recorded on the sea floor, the MT method is also applicable to indirect exploration of the oceanic basement although high frequency shielding by the ocean tends to mask the influence of crustal layers⁹. A recent MT sounding on the North Central Pacific suggests a rapid initial conductivity increase downward through lithosphere and upper mantle, weakening sharply and probably reversing trend around 180±40 km. The resulting high conductivity layer may relate to the partially molten zone

Fig. 1 Location of the observation station ($26^{\circ}35.9'N$, $151^{\circ}09.8'W$). The four elongated figures represent the ratio of the electric field to the magnetic field at right angle for four frequencies and with respect to the azimuth of the electric field. Important bathymetric features are also shown.

or asthenosphere on which the well-lubricated oceanic plate is allowed to slide.

The first suggestion of MT exploration at sea is in Cagniard's original paper², together with a symbolic diagram and the assertion that performing MT soundings on the ocean floor presents no special difficulty. In spite of Cagniard's optimism, as well as the actual simplicity inherent in the principles of the MT method, its application to submarine geophysics has progressed extremely slowly, probably because of the natural hostility of the oceanic environment and the remoteness of the deep sea floor.

The first MT success at sea was scored^{10,11} with a unidirectional MT sounding 600 km off Central California in 1965. In spite of many limitations, this contributed important confirmatory evidence of the considerable difference between continental and oceanic lithospheres, thus enhancing interest in the MT method in offshore geophysics. Newer data¹² collected in 1973 in the West Central Atlantic are being analysed. Nevertheless, the anticipated contribution of sea floor MT to submarine geology and geophysics has remained unproven until very recently.

In autumn, 1976, a new MT sounding was performed in the North Central Pacific with redundant equipment much superior to previously available instrumentation, see Fig. 1. As a result, the electric to magnetic field coherence and concurrently the resolution in characterisation of conductivity structure, improved enough to produce a meaningful structural picture of the local sea floor basement which seems compatible with other accepted knowledge.

Fundamental to this recent advance was the development of instruments with extremely low drift and noise, yet with extremely high resolution (10^{-7} V m⁻¹ and 0.2 nT). Electrode switching by means of a salt bridge chopper^{9,13} permitted essentially total rejection of electrode noise. (The natural signal of the optimum silver-silver chloride electrodes¹³ is typically 10^8 times larger than the signal to be recorded.) Conceptually, the magnetic sensors borrow from high grade fibre and magnet technology already optimised in the time of classical physics and from the most recent advances in modern optometrics.

Recording MT fluctuations

The first 2 weeks of a 3 week redundant recording cross coverage by two electric field recorders and two magnetometers are plotted on Fig. 2. **H** is the magnetic variation to the magnetic North, **D** to the magnetic East, and **Z** downward; **E_x** and **E_y**,

are the horizontal electric field components to the magnetic North and East, respectively.

If Fig. 2 were compared with similar records covering a long period of time the following would be noticed. The daily modulation of the various fields is smooth and regular, particularly with respect to component **D**, although high frequency signals are often present. This relatively quiet behaviour is consistent with the time of collection of data with respect to the 11-yr sunspot and solar storm cycle which had reached its low point. The time reference in the above plot is Hawaii Standard Time (HST). Local noon at our station is therefore slightly early; the maximum descending slope of **D** at midday is slightly ahead with respect to noon, and the difference is consistent with the station longitude.

Although magnetic field disturbances (originated in the ionosphere and beyond, and controlled by fluctuations in the solar wind) as well as their electric field counterpart are numerous on the record, their amplitude is moderate to low, particularly with respect to the higher frequencies: in addition to the inherent low activity characteristic of the present solar cycle state, the shielding of the ocean greatly reduces such fluctuations above a few c.p.h. and essentially suppress them above 15 to 20 c.p.h. Note that most intense electric fields occur when the rate of change of the magnetic field is highest, a fact well exemplified by the rapid excursion of **H** early on 24 and on 27 August and the corresponding large electric spikes in **E_y**, at right angle to **H**.

The power spectra of the four components, **H**, **D**, **E_x**, **E_y**, have been calculated using a fast Fourier transform and band averaging as shown in Fig. 3; note that both spectra and frequency scales are logarithmic. The number of bands resulting in individual frequency estimates is not regular and is roughly five times larger towards the high frequency end. This choice is in part due to our effort to separate subtidal and intertidal bands which must be appreciably contaminated by the signals from strong oceanic tidal motions. (Electric fields of the motional type are generated by the displacement of oceanic water across the field lines of the Earth's main magnetic field.) The tidal bands as well as the relevant spectral estimates are indicated: clearly their energy density is substantially higher than in the adjacent intertidal bands. This excess is split between ionospheric signals from the daily variation and oceanic signals, the latter contributing mostly in **E_x** and **E_y**. Because of the mixing of these processes these bands are not used in the analysis that follows.

The reduced smoothness towards lower frequency is not simply due to the existence of the tidal peaks: in this area the number of Fourier bands forming each estimate is reduced, being limited by the duration of the record available. But, the existence of another source of noise below 0.3 c.p.h. is strongly

Fig. 2 Sea floor electric and magnetic variations for two periods of one week: **H** horizontal magnetic field to the magnetic north, **D** to the east, **Z** downward; **E_x** horizontal electric field to the magnetic north, **E_y** to the east. Time and scales indicated.

Fig. 3 Spectra of electric and magnetic variations. Notice special estimates corresponding to diurnal and semidiurnal tide bands, characterised by the higher energy density resulting from oceanic tidal motions. Δ , D ; \circ , H ; \bullet , E_x ; \blacktriangle , E_y .

suspected, with internal waves and internal tides as prime candidates.

The spectra of H , D and E_x , E_y show very similar behaviour, characterised by a very steep slope toward high frequencies. Also, features in the otherwise rather straight spectral curves, such as a jog around 1 c.p.h. track well, D with respect to E_x , and H with respect to E_y , as expected.

To the extreme right there is a sudden break toward a lesser slope in both H and D , occurring earlier in H than in D . This feature represents the instrumental noise contamination generated by the tape recorder stepping motor. Its greater effect on H compared to D simply relates to the closer proximity of suspension H to the recorder. (Shielding and spacing has suppressed this problem.)

In the following, the individual Fourier spectra are used to calculate cross-spectra and coherencies between all pairs of electric and magnetic components. From these estimates both impedances $Z(f)$ and admittances $A(f)$ are independently estimated according to

$$\begin{vmatrix} E_x \\ E_y \end{vmatrix} = \begin{vmatrix} Z_{xH} & Z_{xD} \\ Z_{yH} & Z_{yD} \end{vmatrix} \begin{vmatrix} H \\ D \end{vmatrix} \quad \text{or} \quad E(f) = Z(f) B(f)$$

and

$$\begin{vmatrix} H \\ D \end{vmatrix} = \begin{vmatrix} A_{Hx} & A_{Hy} \\ A_{Dx} & A_{Dy} \end{vmatrix} \begin{vmatrix} E_x \\ E_y \end{vmatrix} \quad \text{or} \quad B(f) = A(f) E(f)$$

where Z_{xH} etc., A_{Hx} etc., are the elements of the impedance and admittance tensors $Z(f)$ and $A(f)$, with f the frequency, $B(f)$ the vector magnetic field (H , D) and $E(f)$ the vector electric field (E_x , E_y).

If the assumption fundamental to the originally described MT method of an isotropic horizontally layered basement were to be satisfied, in the absence of ionospheric contamination¹⁴, (1) the diagonal elements of $Z(f)$ and $A(f)$ would be zero (the induced electric field is at right angle with the inducing field), (2) the absolute value of the antidiagonal elements would be equal and independent of the reference frame orientation and

(3) $Z(f)$ would be the exact inverse of $A(f)$.

In the presence of a contamination of electric and magnetic signals, equations (1) and (2) relate to the alternate assumptions that all noise affects only the electric, equation (1) or only the magnetic field, equation (2).

The hypothesis of isotropy can be easily tested visually by plotting the ratio of E to B at right angles to E as a function of the azimuth of E for various frequencies, see the result in Fig. 1. The moderate degree of elongation of the expected ideal circular patterns is consistent with a relatively minimal anisotropy. This situation greatly simplifies interpretation of the observed electromagnetic signals.

In the absence of precise knowledge concerning the distribution of noise in E and B we have assumed at first that both E and B are equally affected. We have in addition retained the combination of Z_{xD} and Z_{yH} which, according to Berdichevskiy¹⁵ minimises the effect of possible local heterogeneity of the conductivity distribution. The impedance thus arrived at and used in the interpretation is

$$Z'(f) = (Z_{\text{eff}}/A_{\text{eff}})^{\dagger} \quad (3)$$

where Berdichevskiy's Z_{eff} effective¹⁵ is defined by

$$Z_{\text{eff}} = \frac{1}{2} (Z_{xD} - Z_{yH}) \quad (4)$$

and with

$$A_{\text{eff}} = \frac{1}{2} (A_{Hy} - A_{Dx}) \quad (5)$$

The resulting set of 12 impedances (sometimes called MT ratios, E/B) are plotted in amplitude and phase in Fig. 4 together with error bars at 95% confidence level (the frequency scale is logarithmic). The dotted line represents the impedance function characteristic of an isotropic horizontally layered model optimum with respect to the observed impedances.

Fig. 4 Impedances, or magnetotelluric ratios, derived from crossspectra between electric and magnetic signals, in amplitude (lower box) and phase (upper box). Error bars are indicated at the 95% confidence level. --- \bullet ---, the optimum model; +, observations.

Conductivity distribution and depth

The method used to select the conductivity distribution with depth that best fits the observations will now be outlined briefly; 12 frequency estimates are available providing 12 amplitudes and 12 phases, thus a total of 24 constraints in a least square fit of the model predictions. The allowable number of model parameters thus must be substantially less than 24. With each horizontal layer involving thickness and conductivity—thus two parameters—a realistic model should include appreciably less than 12 layers. Using n layers with pre-determined thicknesses and conductivities the resulting impedances are calculated. The mismatch model to observation is estimated in terms of the variance between observed and predicted impedance functions.

The effect of changing the conductivity on the variance is then studied for each layer and improved conductivity values are updated accordingly. Convergence is rapid for the layers well characterised by the available cross-spectral estimates. From this rate of convergence, or equally well from the sensitivity of the variance to small conductivity changes, important implications result about the validity of the optimum model and the range of conductivity values acceptable in the various layers.

Following these guide lines we propose for the conductivity dependence with depth and for its range of uncertainty the five layer model with infinite half space substratum shown on Fig. 5. The layers are horizontal and isotropic. Their thicknesses are, from top downwards 60, 80, 80, 100 and 150 km respectively.

The layers best defined by the set of available impedances and

Fig. 5 Optimum six layer model of an isotropic, horizontally layered sea floor structure. Shaded area indicates range of uncertainty. Best resolved layer is layer 3, with a significantly high conductivity probably related to the asthenosphere. Estimates from other authors also shown.

in the order of decreasing resolution are 3, 2 and 4; the increased uncertainty in layer 1 adjacent to the ocean results from the high frequency cut off due to oceanic shielding, while decreasing resolution below layer 4 is a consequence of the low frequency impedance unreliability, itself related to the finite record length and increased oceanic motional noise. The influence of this signal is strongly supported by the much higher interpretability of the impedance estimates when noise contamination is assumed to be affecting mainly the electric field.

Earlier estimates of the Earth's electrical conductivity with depth are also shown in Fig. 5 as interpretative background, namely global averages proposed by Lahiri and Price¹⁶ (LP) and Parker¹⁷ (P), Larsen's profile below Hawaii¹⁸ (L) and Filloux's profile¹⁹ (F) 600 km offshore from Central California. The implied conductivity at the observation site is intermediate between that proposed by Lahiri and Price on the low side and that of Parker on the high side. A conductivity maximum is strongly suggested by the high conductivity average over an 80 km thickness in layer 3, with the value of 0.065 S m^{-1} . The actual conductivity maximum may, of course, be much higher, with a correspondingly smaller thickness. Its most probable depth of occurrence ranges within $180 \pm 40 \text{ km}$.

Although not very well resolved, the crustal conductivity is moderate to low, which is consistent with a sediment layer only a few hundred-metres thick and with the relatively old age of the local lithosphere: the matching seafloor spreading magnetic anomaly¹⁹ corresponds to reversal number 31 and to a plate age of 72 Myr (ref. 20).

The probability of a high conductivity tongue within layer 3 should be tested against processes implied by our present understanding of plate tectonics and ocean floor spreading, and against profiles of other physical properties of terrestrial materials over the same depth and, if possible, the same area.

A most attractive and immediate implication is that layer 3 contains the shear and partly molten layer or asthenosphere between mantle and lithosphere which permits plate motion. This view is in rough agreement with the range of occurrence of the oceanic low shear velocity layer²¹, namely 130–270 km. It is also compatible with Odegard's interpretation of the Cannikin/airborne experiment²² which suggests for an area broadly inclusive of our station, a low P-wave velocity layer extending from 210 to 320 km. Indirect estimates, however, of the lithospheric thickness^{23,24} suggest only 75 km for the local plate age. The discrepancy may be more apparent than real, relating to the still little known thickness of the asthenosphere in general and to the presently limited information concerning electrical conductivity of mantle materials, itself closely dependant on temperature and small changes in composition³.

The other MT profiles available from not-too-distant areas, that of Larsen (L), Fig. 5, and that of Filloux (F), like the present one predict or imply high conductivity layers and probable inversions. It is logical to attempt to relate these features and to tentatively predict that their significance may have something in common. Certainly the very high conductivity at a very shallow depth in the F profile is compatible with a much younger lithospheric age, about 32 Myr. The extremely high conductivity maximum in Larsen's model occurs at a considerably greater depth and may relate to the origin of the Hawaiian island chain.

In conclusion, and to give the foregoing analysis a realistic perspective, future MT sea floor work can be carried out with a considerably improved efficiency. Specifically, the following advantages can be readily attained: (1) longer records, up to one year, can be achieved with existing technology; (2) the frequency range can be readily extended upward by a factor of 4 and perhaps occasionally by a factor of 8 to 16; (3) broad coverage with instrumental arrays shall permit study of multidimensional structures such as spreading centres, subduction zones where old crust is consumed and trenches, island chains and arcs; and (4) magnetic activity, at a low during the present experiment shall progressively rise during the next five years, providing more energetic ionospheric fluctuations, thus

allowing improved resolution in general, and particularly in shallower crustal structures.

I thank Drs Larsen and Winter for constructive criticisms and programming advice, L. Green and H. Moeller for technical assistance. This work was supported by the USNSF.

Deep-sea carbonate and the deglaciation preservation spike in pteropods and foraminifera

W. H. Berger

Scripps Institution of Oceanography, University of California, San Diego, La Jolla, California 92093

The aragonite compensation depth fluctuated considerably during the last 20,000 yr. This fluctuation culminated in a preservation spike at about 14,000 yr BP. The aragonite preservation stratigraphy parallels that in calcitic foraminifera, and constitutes part of a world-wide phenomenon signalling considerable changes in ocean chemistry and providing a useful tool for correlation.

THERE is abundant evidence that the effects of carbonate dissolution on the deep sea floor changed considerably as a result of Pleistocene climatic fluctuations. Within the last 20,000 yr, there has been a drastic worldwide drop of the aragonite compensation depth and of foraminiferal preservation levels during deglaciation, and a subsequent rapid rise to the present position. This fascinating phenomenon, which was a geologically almost instantaneous preservation pulse of 'spike', is the subject of this article.

The deglacial preservation spike was reported by the marine geology group at Kiel, working from the research vessel Meteor on the continental slopes off Portugal and Morocco^{1–4}. It expresses itself most commonly as a pteropod-rich layer, at the very end of the last glacial. The interpretation of this event is complicated by evidence for downslope redeposition. However, in many cases the pteropod layer does not seem to be associated with redeposited material, and a change in dissolution effects seems indicated as pointed out by Diester-Haass⁵. More recently, she proposed mass mortality of pteropods to explain the phenomenon⁶.

Recent evidence from the western equatorial Pacific^{7–8} indicates that the deglacial preservation spike is a world-wide event. Shackleton⁹ has drawn attention to this possibility and has commented on some geochemical implications of such an event.

Before turning to such implications, of which there are many, let us review briefly the evidence for the preservation stratigraphy from the last glacial to the present, that is, the last 20,000 yr.

Evidence for preservation stratigraphy

A drastic rise in the calcite compensation level at the glacial-Holocene boundary was recognised in the North Pacific¹⁰ on the basis of published foraminiferal data^{11,12}. Quite generally, there are fewer calcareous foraminifera in

Holocene sections of cores from the North Pacific than in the underlying glacial ones^{13,14}; the change has been dated at 12,500 yr BP¹⁵. Analogous observations were made elsewhere (East Pacific Rise¹⁶; Equatorial Pacific¹⁷; Andaman Sea¹⁸). The recognition of a Holocene dissolution pulse led to a reinterpretation of Arrhenius's carbonate cycles in the equatorial Pacific¹⁹ in terms of dissolution cycles^{20–23} with increased dissolution during interglacials, as suggested earlier by Olausson²⁴. Subsequently it was discovered that the dissolution cycles appear shifted with respect to the glacial-interglacial cycles^{25–27}. One type of shift can be produced by centering a carbonate preservation maximum on deglaciation, some 4,000 yr after the glacial maximum.

On examining the literature, it becomes evident that such a preservation spike exists not only in the eastern North Atlantic^{1–4} and in the west equatorial Pacific^{7,8}, but also in the Caribbean and in the Gulf of Mexico²⁸, on the western slope of India^{29,30}, and in many places in the deep sea, although here slow sedimentation rates and wide spacing of sampling intervals make recognition subject to doubt in each individual case (Atlantic: refs 31–33; Pacific refs 22, 23, 25).

The magnitude and the timing of the preservation pulse can be assessed. The pteropod data from the slope off NW Africa^{3,4} indicate that the euglacial ACD (lower depth limit of pteropods) stood at 1.5 km, the deglacial one at 3.5 km, and the postglacial one at 0.5 km (Fig. 1a). The corresponding ACD levels in the western equatorial Pacific are 1 km (?), 1.7 km, and 0.5 km (Fig. 1b). Similar fluctuations can be documented elsewhere and in shells other than pteropods (Table 1).

It will be noted that preservation during pre-deglacial

Table 1 Magnitude of preservation spike in calcareous shells

Type of level	Area	Depth (km) during			Source
		Post-G.	De-G.	Eu-G.	
ACD	Off NW Africa	0.5	3.5	1.5	Refs 3, 4
ACD	Off Portugal	1.1	3.6	2.8	Ref. 2
ACD	Off W India	0.3	2.5	1.2	Ref. 29
ACD	W. Eq. Pacific	0.5	1.7	1(?)	This article
RCD	W. Eq. Pacific	2.8	3.8	3.1	This article

ACD: lower depth limit of pteropods. RCD: lower depth limit of *Globigerina rubescens*, a planktonic foraminifer that is highly susceptible to dissolution. Post-G.: postglacial.

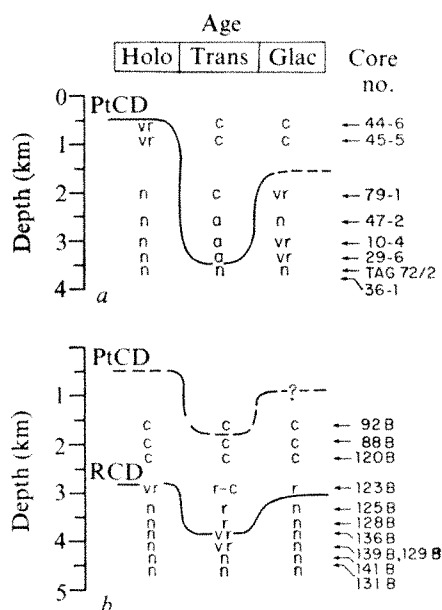

Fig. 1 Excursion of the compensation depth for pteropods (PtCD) and for *Globigerina rubescens* (RCD) during the transition period from glacial to Holocene time. *a*, Off NW Africa, based on data given by Diester-Haass (refs 3 and 4). *b*, Western equatorial Pacific, own data.

('euglacial') is indeed better than during postglacial time, in agreement with earlier assessments based on accumulation rate comparisons²⁰. However, the preservation story is clearly more complicated than a simple glacial-interglacial dichotomy would suggest.

The timing of the preservation spike is of crucial importance if the geochemical driving mechanisms are to be discovered. The data in Kudrass² suggest that the spike is centred in 13,500 yr BP. Our own data from the equatorial Pacific⁸ and those of Chen and of van Donk (in ref. 20) indicate maximum preservation during maximum change in the oxygen isotope signal. In the Gulf of Mexico, this period of maximum change is dated at about 15,000 yr to 12,500 yr BP^{34,35}, although the exact timing is in some dispute. In the west equatorial Pacific, the period of maximum change (and the preservation spike) seems to be close to 14,000 yr BP (ref. 8). The same period is centred between 13,500 and 14,000 yr BP in the dated isotope sequence of a core in the equatorial Atlantic²⁶. One may conclude that the spike has its maximum at about 14,000 yr BP.

The spike is narrow, perhaps no more than 1,000 yr wide. Considering the effects of bioturbation, the resolution of such an event in deep sea cores represents the limit for this type of record. A further constraint on the timing is given by the rapid increase of dissolution following this spike, starting at about 13,000 yr BP^{14,15}. In fact, the very recording of the rapid onset of the dissolution pulse in deep sea sediment, despite benthic mixing and the presence of good preservation immediately preceding it, strongly suggests a flip-flop situation, with a dissolution spike immediately following a preservation spike.

Geochemical and stratigraphical implications

What are some of the geochemical and stratigraphic implications of the deglacial preservation spike?

Fundamentally, we can enhance preservation of carbonate in deep waters by increasing saturation, by decreasing the speed of bottom currents, or by suddenly increasing sedimentation rate, for example, by redeposition. I suggest that a combination of these factors is at work, rather than any one process. First, let us examine saturation.

The thermodynamic equations on which saturation determination depends contain the following alterable terms³⁷: (1) partial pressure of CO₂, and (2) temperature and chlorinity. Availability of CaCO₃ (3) enabling reactions to proceed towards equilibrium, also is a variable in the real ocean. We see that the first item refers to a property of the atmosphere, the second to the water itself, and the third to conditions at the sea floor.

To enhance preservation then, the following possibilities arise:

- Lowering of the CO₂ pressure in the atmosphere. Shackleton⁹ has suggested that the rapid growth of the biosphere during deglaciation would lead to extraction of CO₂ from the atmosphere-ocean system, and hence result in improved preservation of carbonate. Both a change from glacial aridity to postglacial humidity in tropical latitudes³⁸ and the recession of tundra and ice would be responsible for this 'biosphere effect'. If one adds the dead carbon ('thanatosphere') that would build up together with the growing forests and below the rising sea level, this effect could indeed be substantial—of the order of 1% of the entire ocean-atmosphere CO₂ content. In areas of gentle depth gradients of saturation, such a change could result in marked excursions of the dissolution level. One problem with accepting Shackleton's biosphere effect as the main or sole factor is the timing of the major changes in floral cover. Apparently this major change is not centred on 14,000 yr BP, but rather occurs between 13,000 yr and 10,000 yr ago^{39,40}, that is, during the dissolution pulse rather than the preservation spike.

- Increase in temperature of deep ocean waters. Weyl⁴¹ speculated that abyssal waters would have warmed during glacials and Worthington⁴² pointed out that a low-salinity meltwater lid due to deglaciation would lead to stagnant bottom waters, affecting carbonate preservation. There is indeed evidence for such a glacial warming of deep water⁴³⁻⁴⁵, at least in the Atlantic Ocean. This 'glacial bottom water effect' does not seem to be focused enough to account for the preservation spike, although it must be taken into account in the overall glacial-postglacial preservation fluctuations.

- Decrease of the chlorinity of deep ocean waters. The addition of meltwater eventually decreases chlorinity by some 3%. This is most likely done with run-off water, which brings its own dissolved load of calcium carbonate. The exact effect on saturation of the ocean as a whole would seem to depend on the magnitude of this load, which would depend on the rate of recycling of the water, through continuous evaporation and precipitation, during the time of net addition to the ocean, and on the rate of concomitant chemical erosion.

- Increase of availability of CaCO₃ in abyssal depths. There is considerable evidence for large-scale redeposition of shallow water sediments in the Late Pleistocene, including pteropod-rich sediments^{2-4,15,28,35}. Such transport makes carbonate particles available at abyssal depths. Here bottom waters are greatly undersaturated and are able to dissolve such particles at a maximum rate. On rising, therefore, these waters will quickly reach saturation values which preclude rapid attack of calcareous shells. The timing of this 'neutralisation' of abyssal waters seems to be correct.

Two more possibilities can be added, considering that the ocean is not in equilibrium:

- Decrease in the rate of extraction of carbonate in surface waters, by calcareous organisms. A reduction of precipitation of shells in surface waters will increase the overall saturation of the ocean with the respective substance and therefore enhance preservation^{46,47}. (Thus, the relationship between overall fertility and preservation of biogenous sediments is exactly the reverse of that usually suggested.) It is possible that a rapid dumping of meltwater, combined with incomplete mixing, would temporarily reduce produc-

Fig. 2 Compensation depth fluctuations as a response to a disturbance (for example change in supply). The amplitude of the response is strongly governed by the depth gradient of dissolution, and its relationship to the disturbance. The reaction of the system to a given disturbance provides insights into the state of undersaturation.

tivity, although there is no evidence for such a 'fertility effect'.

● Increase in the rate of supply of alkalinity to the ocean as a whole. The redeposition of shelf carbonates (the fourth item, above) constitutes addition of alkalinity. Also, the alkalinity supply may be increased during deglaciation by an increase in the suspended and dissolved load of river input, through erosion of glacial weathering products (loess, calcareous desert crusts, morainal debris). If conditions fluctuated between arid and humid and before the plant cover could re-establish itself, this would provide for maximum erosion. Also, sea level was still considerably depressed, leaving the upper shelf areas exposed for erosion, and facilitating bypassing of the lower ones by the sediment introduced. Considering the evidence for transport of terrigenous and shelf deposits into abyssal waters, the 'neutralisation effect' could have operated earlier, on a reduced level, throughout glacial conditions, aided by additional supply whenever arid conditions changed to humid.

It should be noted that the type of stagnation visualised by Worthington⁴², due to a hypothetical meltwater lid, should lead to a decrease in bottom currents (enhancing preservation) but also to a build-up of CO_2 (enhancing dissolution). In this scenario, when ocean mixing finally catches up with the meltwater, CO_2 is released to the atmosphere, and a climatic optimum ensues. Increased CO_2 , together with rapid extraction of carbonate on the flooded shelves, probably accounts for the dissolution pulse following the preservation spike.

It is obviously tempting to go on speculating about the relationship between CO_2 fluctuations and preservation and dissolution pulses, especially in view of the man-made CO_2 input to the atmosphere and its presumed ultimate effects on carbonate deposition and climate⁸. Suffice it to say that the type of analysis presented here, which is an example of preservational stratigraphy, has considerable potential for palaeoclimatic studies in the deep sea as well as in shallow waters⁴⁴.

The most obvious use of the preservation spike is for correlation and dating of deep sea cores. Relative preservation aspects can be determined extremely rapidly by visual inspection, for example, by noting the degree of fragmentation of foraminifera in the fine sand fraction. Thus, the peak preservation is easily found. We have already made considerable use of this method in the deep-sea sediment

laboratory at the Scripps Institution of Oceanography. A word of caution is in order, however. Before determining sedimentation rates by this method, the displacement of a spike by benthic mixing must be considered. This displacement is downward, by up to one mixed layer thickness, depending on the ratio between the thickness of the layer and the thickness corresponding to the actual duration of the event. For example, a rate of 1.93 cm per 1,000 yr would be calculated for the pteropod-containing core Bx 92 (Fig. 1b), if the centre of the pteropod preservation spike at 27 cm is divided by 14,000 yr, the estimated age of the event. Allowing for a mixed layer of 6 cm (ref. 17), and a duration of the spike of 2,000 yr (3–4 cm), the offset is 4.5–4 cm (mixed layer thickness minus one-half the width of the event, see ref. 49). Thus, the actual sedimentation rate, under these assumptions, is closer to 1.6 cm per 1,000 yr than to 1.9 cm per 1,000 yr, a non-trivial correction. The problem is not restricted to the dating method presented here, but is of a general nature. It is negligible only in cores with high sedimentation rates.

One final note of caution in interpreting the significance of preservation fluctuations: a change in preservation is a result of both the condition of the system (sensitivity, that is, depth gradient of potential dissolution rate) and the strength of the agent of change (disturbance, resulting in a change in the record). Depth gradients of dissolution can change both in space^{30–33} and in time^{34–36}. Disturbances of similar magnitude, therefore, can produce greatly differing amplitudes in preservational signals (Figs 2a, b).

In fact, the response amplitudes of high frequency ACD and CCD fluctuations through time may be a useful tool for determining variations in the strength of the depth gradient of undersaturation in the deep ocean. For example, relatively small disturbances in Late Cretaceous carbonate sedimentation in the central Atlantic apparently were responsible for large CCD excursions³⁷ presumably due to high sensitivity of the system (gentle dissolution depth gradient). In comparing the record of marginal seas to that of the open ocean, it must be kept in mind that these seas may not play exactly the same tune as the open ocean. Thus the Late Pleistocene and Holocene preservation stratigraphies of the Mediterranean, the Red Sea, the Sea of Japan and the Arctic Ocean are entirely different from the one described here (see refs 28, 58, 59).

This research was supported by the National Science Foundation and by the Office of Naval Research. Parts of the manuscript were written at the Geologisches Institut in Kiel, Germany. I thank Professor E. Seibold and my other colleagues in Kiel for their hospitality.

The Institute for Cancer Research, 7701 Burholme Avenue, Fox Chase, Philadelphia, Pennsylvania 19111

The crystal structure of a 3 : 2 complex of the frameshift mutagen proflavine with the dinucleoside phosphate cytidylyl-3'-5'-guanosine has been determined. The complex has one drug molecule intercalated between Watson-Crick base pairs of the nucleotide duplex. The other two proflavine molecules are bound to the exterior of the miniature double helix. The orientation of the base pairs in this miniature double helix has aspects similar to that found in RNA II.

It is well established that many drugs and carcinogens act by binding to nucleic acids; both nuclear double-stranded DNA and RNA have been shown to be targets for such interactions^{1,2}. Many such drugs are characterised by a planar aromatic structure, and the acridines, in particular, have been the subject of much study¹. The concept of drug intercalation between adjacent base pairs of the nucleic acid, first introduced by Lerman³, accounts satisfactorily for many observed properties of drug–nucleic acid complexes, and is widely accepted. Intercalation is believed to be responsible for the activity of many of these drugs as frameshift mutagens^{4–6}. In addition, intercalation, and the subsequent unwinding of nucleic acids, has emerged as an important tool in the study of superhelicity^{7,8}.

Intercalation necessitates an alteration in the geometry of the double helix at (and, presumably, adjacent to) the actual binding site. In normal B DNA the turn angle of rotation between adjacent nucleotide residues is 36°. In the original model for intercalation³ the helix uncoils by 45° from this value. Subsequent studies^{9–12} using various drugs including proflavine provide support for the intercalation hypothesis although the degree of concomitant unwinding remains uncertain with values ranging from –45° to 12°. Linked atom refinement techniques¹³ have been used to define further both the degree of unwinding as well as the exact conformational features of DNA complexed with proflavine.

Proflavine (Fig. 1) is involved in more than one mode of

binding^{1,14}. In addition to the strong intercalative process which occurs at low drug levels, there is a weaker binding of the drug, presumably external to the helix. Temperature-jump relaxation kinetics data^{15,16} show, however, that the strong binding process is itself a complex one, involving as an initial step, externally-bound drug molecules. It is apparent that a realistic visualisation of proflavine–DNA binding should involve both factors.

Fig. 1 A proflavine cation.

We have determined the crystal structure of a complex between proflavine and cytidylyl-3',5'-guanosine (CpG) (Fig. 2), in the hope that this would serve as a model for proflavine–nucleic acid interactions. We were encouraged in this belief by analyses of two other dinucleoside monophosphates^{17,18}, which showed the features of an RNA-like miniature double helix, and of several drug–dinucleoside phosphate complexes^{19,20} which demonstrated intercalative binding. The proflavine–CpG complex was deliberately produced without any heavy atoms so as to avoid the possibility that they might perturb the structure.

Crystallographic analysis

Large, well formed single crystals of the complex were produced from an aqueous solution of proflavine hemisulphate and free acid CpG. The crystals showed triclinic symmetry, space group *P*1, with cell dimensions *a* = 16.098 Å, *b* = 16.755 Å, *c* = 12.933 Å, α = 112.67°, β = 113.69° and γ = 99.36°. As has been observed with other dinucleoside phosphates²¹, however, the diffraction pattern displays pronounced pseudosymmetry such that it

Fig. 2 The cytidyl 3',5'-guanosine anion.

was possible to index the reflections in a monoclinic cell, space group $C2$, with cell dimensions $a = 29.487$ Å, $b = 12.933$ Å, $c = 16.883$ Å and $\beta = 121.94^\circ$. Because of this ambiguity, the intensity data were measured on the basis of the space group $P1$. A crystal was sealed in a glass capillary in which mother liquor was included.

A total of 5,621 independent reflections was measured, to a limit of 1 Å resolution, on an automatic four-circle diffractometer using $\text{CuK}\alpha$ radiation. Of these, 4,073 reflections were considered to have intensity significantly greater than background. In addition, Friedel mates for 356 reflections were measured and the agreement, R_{sym} , for these 356 Friedel pairs was found to be 0.038. When the reflection data were transformed to space group $C2$, the agreement among the symmetry-related reflections was 0.139. The fact that the agreement for symmetry related reflections for space group $P1$ was significantly better than for space group $C2$ was taken as a strong indication that space group $P1$ is more probable. Accordingly, the structural analysis was carried out in the latter space group.

Numerous attempts at structure solution by direct and search methods were unsuccessful. The structure was eventually solved by location of the phosphorous atoms using the high resolution Patterson technique²², followed by a number of cycles of (E and F) Fourier syntheses to determine the rest of the structure. Early stages of the analysis of the crystal structure were greatly facilitated by the use of the interactive computer graphics system²³ at the Institute for Cancer Research. This permitted the rapid detailed evaluation of possible structural fragments at each stage of the analysis. Least squares refinements, as yet incomplete, have reached an R of 0.155 and the overall structure is well ordered; only a few atoms display high thermal motion.

Proflavine interacts with miniature double helix in several ways

A projection of the structure is illustrated in Fig. 3. It is a 3:2 proflavine-CpG complex and represents the first reported crystal structure of drug-dinucleotide complex which does not have 2:2 stoichiometry. The two dinucleotides are hydrogen bonded to form a miniature double

helix with Watson-Crick base pairs, separated by 6.8 Å. One of the proflavine molecules is symmetrically intercalated between the base pairs and protrudes into the wide groove. Each amino group of this proflavine forms a hydrogen bond to a phosphate oxygen on either side of the duplex. These interactions, therefore, probably serve to stabilise the observed symmetry of intercalation. The other two proflavine molecules stack asymmetrically above and below the miniature double helix. The asymmetry is such that these proflavines tend to stack more over the guanine residues thereby preserving the pseudo-twofold symmetry which may be described as an axis perpendicular to the helix axis and lying along the $\text{C}(9)\text{--N}(10)$ vector of the intercalated proflavine molecule.

Fig. 3 A view of the structure of the complex, tilted slightly from the view parallel to the mean planes of the base pairs. Dotted lines represent hydrogen bonds. Nitrogen and phosphorus atoms are black and oxygen atoms are stippled.

Inspection of the non-intercalated proflavine molecules (translated to adjacent unit cells) shows that the molecules also bind externally to the duplex through a system of hydrogen bonding (Fig. 4). The external binding to the backbone of the duplex may be described by four unique hydrogen bonds—two from proflavine amino groups to phosphate oxygens and two more from proflavine amino groups to the $\text{O}(2')$ hydroxyl oxygens of the cytosine riboses. Note that the phosphate oxygens that are hydrogen bonded in this manner are also those that are hydrogen bonded to the amino groups of the intercalated proflavine

Fig. 4 A view of the structure, looking perpendicular to the planes of the base pairs. The two phosphorus atoms are shown in black, one as a heavy open circle and the other as a large solid circle. The atoms of the uppermost base pair are also in black and the intercalated proflavine has black bonds.

molecule. The packing in the crystal structure is such that the non-intercalated proflavines link adjacent base-paired duplexes by these external hydrogen bonds; when one amino group of an external proflavine molecule is hydrogen bonded to a phosphate oxygen, the other amino group of that proflavine molecule is hydrogen bonded to an O(2') hydroxyl oxygen of a neighbouring duplex (Fig. 5). The overall effect is a pattern of extensive cross-linking between adjacent miniature double helices.

The crystal structure of the complex is heavily hydrated, with 24 water molecules associated with each unit. This large degree of hydration lends credence to the relevance of this structure to nucleic acid-drug complexes. A full description of the many interactions involved will be published elsewhere.

Proflavine stacks with base pairs and also with other proflavines

THE sequence of stacked polycyclics is proflavine-base pair-intercalated proflavine-base pair-proflavine-proflavine-base pair-intercalated proflavine, and so on, so that proflavine-proflavine stacking also occurs (Fig. 5). In this case the long axes of the proflavine molecules lie at approximately 83° to each other. This is a different situation from that found in proflavine hydrochloride²⁴ where this angle is 180° and in proflavine hemisulphate where this angle is 150° (refs 2, 25). The skewness of stacking of proflavine molecules probably results from the fact that the terminal amino groups of proflavine are hydrogen bonded to phosphate oxygen atoms and to ribose O(2') hydroxyl groups. These hydrogen bonds position the molecule with respect to the base pairs and, to satisfy the crystallisation conditions, proflavine-proflavine stacking occurs as best it may.

The 3:2 nature of this complex, containing two mono-ionised anions of CpG (Fig. 2), suggests that one of the three proflavine molecules carries no charge. By symmetry one would expect this to be the intercalated proflavine molecule. Assignment of these charges must await further refinement and the location of hydrogen atoms.

The miniature double helix has unexpected features

Each base pair is twisted in a propeller-like fashion, much as has been found in other dinucleoside phosphate structures. The spacing between base pairs is 6.8 Å, as would be expected for a complex of this sort. What is not expected, however, is that the orientation of the two base pairs has aspects similar to that found in normal, uncomplexed RNA 11 (ref. 26). That is, the angle between the vectors connecting the glycosidic carbon atoms within each base pair is 33°, not the 8°–10° values found in the structures of iodo-CpG-ethidium bromide and iodo-CpG-9-amino-acridine.

Moreover, instead of having C(3') *endo* 3'-5' C(2') *endo* mixed sugar pucker²⁷, all the sugars are C(3') *endo*. The stretching (rather than unwinding) of this miniature helix is accomplished by systematic changes in the backbone and glycosidic angles. The implications of this surprising result with respect to the unwinding of polynucleotide structure are under investigation.

The results of this analysis allow us to explain various phenomena associated with proflavine complexation to nucleic acids. We have defined in geometric terms two modes of binding: (1) symmetrical intercalation with hydrogen bonding to the phosphate groups, and (2), hydrogen bonding to phosphate and ribose O(2') hydroxyl atom external to the helix. It is known that when acridines are used to stain cells, the RNA complex shows a red fluorescence whereas the DNA has a green fluorescence¹.

Fig. 5 A diagrammatic representation of the packing of the CpG and proflavine ions in the crystal lattice.

This difference may be explained, in part, by the hydrogen bonding between the O(2') hydroxyl of the ribose and the amino nitrogen of the proflavine since there is no O(2') hydroxyl group in DNA. The structure also shows the nature of the aggregation of the proflavine molecules themselves (see Fig. 5). Finally, the similarity of the orientation of the overlapping base pair planes to those in RNA 11 (as measured by the vectors between the C(1') glycosidic atoms), implies that proflavine does not unwind the helix.

This work was supported by grants CA-05322, CA-10925, GM-21589, CA-06927 and RR-05539 from the US NIH, an appropriation from the Commonwealth of Pennsylvania, and by grants from the Cancer Research Campaign, the SRC, and the Lawson Tait Trust. S.N. is grateful to the Royal Society and the Cancer Research Campaign for travel grants, and to the Institute for Cancer Research for their hospitality. We also thank G. M. Sheldrick, M. Spencer, L. Wakelin and M. Waring for helpful comments. *Note added in proof:* We have been informed by Alden and Arnott that they have developed a model for A DNA-proflavine binding which has many features similar to our structure. Sobell *et al.* have given a preliminary structural report of a 2:2 proflavine-iodo CpG complex (American Crystallographic Association meeting, August 1977).

Orientation of cell-surface antigens in the lipid bilayer of lymphocyte plasma membrane

Frank S. Walsh* & Michael J. Crumpton

National Institute for Medical Research, Mill Hill, London NW7, UK

Human HLA-A, B, C and Ia antigens were labelled by lactoperoxidase-catalysed iodination of the inner surface of lymphocyte plasma membrane and thus are transmembrane proteins. In contrast, membrane-bound human IgM and mouse IgM, IgD and Thy-1 antigen were not labelled on the inner membrane surface.

AN important role of the plasma membrane is to transmit biochemical signals generated by ligand–receptor interaction at the cell surface across the lipid bilayer and into the cell¹. The elucidation of the mechanisms of transmembrane informational transfer depends ultimately on the designation of the orientation of the membrane proteins in the bilayer. In this respect the transmembrane proteins are especially favoured candidates since they are exposed on both the outer and inner (cytoplasmic) membrane faces. Thus, this orientation has apparently been universally adopted by membrane transport proteins^{2,3}. It is, however, evident that transmembrane proteins are not a prerequisite for signal transmission and that other mechanisms also exist. For instance, the biological effects of certain outer cell surface hormone receptors are believed to be mediated by interaction with cytoplasmically disposed adenylate cyclases⁴.

In view of the apparent functional importance of transmembrane proteins, there are strong incentives to develop methods for their identification. One possible way is by comparing the patterns produced by covalent labelling of the outer and inner surfaces of cells or plasma membranes^{5–6}. Application of this approach to erythrocytes^{7–11} has demonstrated that both of the major erythrocyte glycoproteins, glycophorin and band 3, are transmembrane molecules. The results of these studies have led to the proposals that all membrane glycoproteins have a transmembrane orientation, that the non-glycosylated proteins are exposed on the inner surface only and that no protein is present exclusively on the outer surface unless it is associated with a glycoprotein which spans the lipid bilayer^{12,13}. The notable successes that have been achieved with erythrocytes are primarily due to two factors—the lack of intracellular membranes and the ready availability of sealed ‘inside-out’ membrane vesicles for labelling the inner membrane surface^{7,8}. Several proteins in various other systems have also been shown to be transmembrane—for example, (Na⁺, K⁺)-dependent ATPase¹⁴, intestinal brush border aminopeptidase¹⁵, cytochrome *c* oxidase¹⁶, Semliki forest virus coat protein¹⁷ and rhodopsin¹⁸. No generally applicable method for their detection has, however, emerged with the result that knowledge of the orientation of membrane proteins of nucleated cells has proceeded slowly.

Designation of transmembrane proteins

We describe here a method for defining the transmembrane proteins of lymphocyte plasma membrane. Lymphocytes were chosen for study because their surface structure regulates many

biological effects (for example, activation by antigen, ‘patching’ and ‘capping’ of surface receptors) and includes many antigens of known specificity (for example, Ia and Thy-1 antigens, IgM and IgD). Also, well-characterised preparations of the surface membrane are available¹⁹. The approach adopted for designating the orientation of membrane proteins relied on lactoperoxidase-catalysed iodination for covalent labelling, and the availability of inside-out membrane vesicles that were sealed to lactoperoxidase. Lactoperoxidase-catalysed iodination was selected in preference to other techniques because the conditions favouring vectorial labelling have been clearly defined²⁰. In particular, the free iodide concentration was adjusted to less than 10^{−6} M to promote iodination via an impermeable enzyme-activated iodine complex²⁰. The procedure suffers, however, from a fairly high degree of selectivity in that only proteins with exposed tyrosine and possibly histidine residues are labelled. A method for the preparation of inside-out vesicles of pig lymphocyte plasma membrane has been described previously²¹. Although the vesicles were permeable to trypsin and concanavalin A, a subpopulation of vesicles has been selected by dextran density gradient centrifugation that were sealed to dextran of 10,000 molecular weight and also, by implication, to lactoperoxidase (molecular weight 78,000). Lactoperoxidase-catalysed iodination of these vesicles followed by affinity chromatography on concanavalin A–Sephacrose gave a different pattern of labelled polypeptides than that obtained with viable pig lymphocytes²². At least eight labelled polypeptides of each sample comigrated on polyacrylamide gel electrophoresis in sodium dodecylsulphate and were, consequently, judged to have a transmembrane orientation. A disadvantage of this study was the inability to equate any defined surface component with a particular iodinated polypeptide. This problem has been circumvented by using antisera against defined surface components to precipitate the homologous antigen from ¹²⁵I-labelled, inside-out membrane vesicles after solubilisation in sodium deoxycholate. The orientation of the following cell surface antigens have been analysed using this approach: the HLA-A, B, C and Ia antigens, and IgM of cultured human lymphoblastoid B1 8 cells, as well as the Thy-1 antigen of mouse thymus cells, and IgM and IgD of mouse spleen cells.

Cell surface antigens

The choice of cell-surface antigens for study was determined by the availability of cells and specific antisera. The human B-lymphoblastoid cell line B1 8 was chosen because it represents a well-documented source of HLA-A, B, C and Ia antigens and membrane-bound IgM^{23,24}. Mouse thymus and spleen cells have the advantage of being a relatively rich source of Thy-1 antigen²⁵ and membrane-bound IgM and IgD²⁶ respectively. Goat anti-(human β_2 -microglobulin) serum raised by immunisation with purified urinary β_2 -microglobulin was used as a ligand for the human HLA-A, B and C antigens. This choice is based on the observation that β_2 -microglobulin is non-covalently associated with the products of the HLA-A, B and C genes on the cell surface²⁷. The antiserum was shown to be monospecific on the

* Present address: Laboratory of Biochemical Genetics, National Institutes of Health, Bethesda, MD 20014, USA

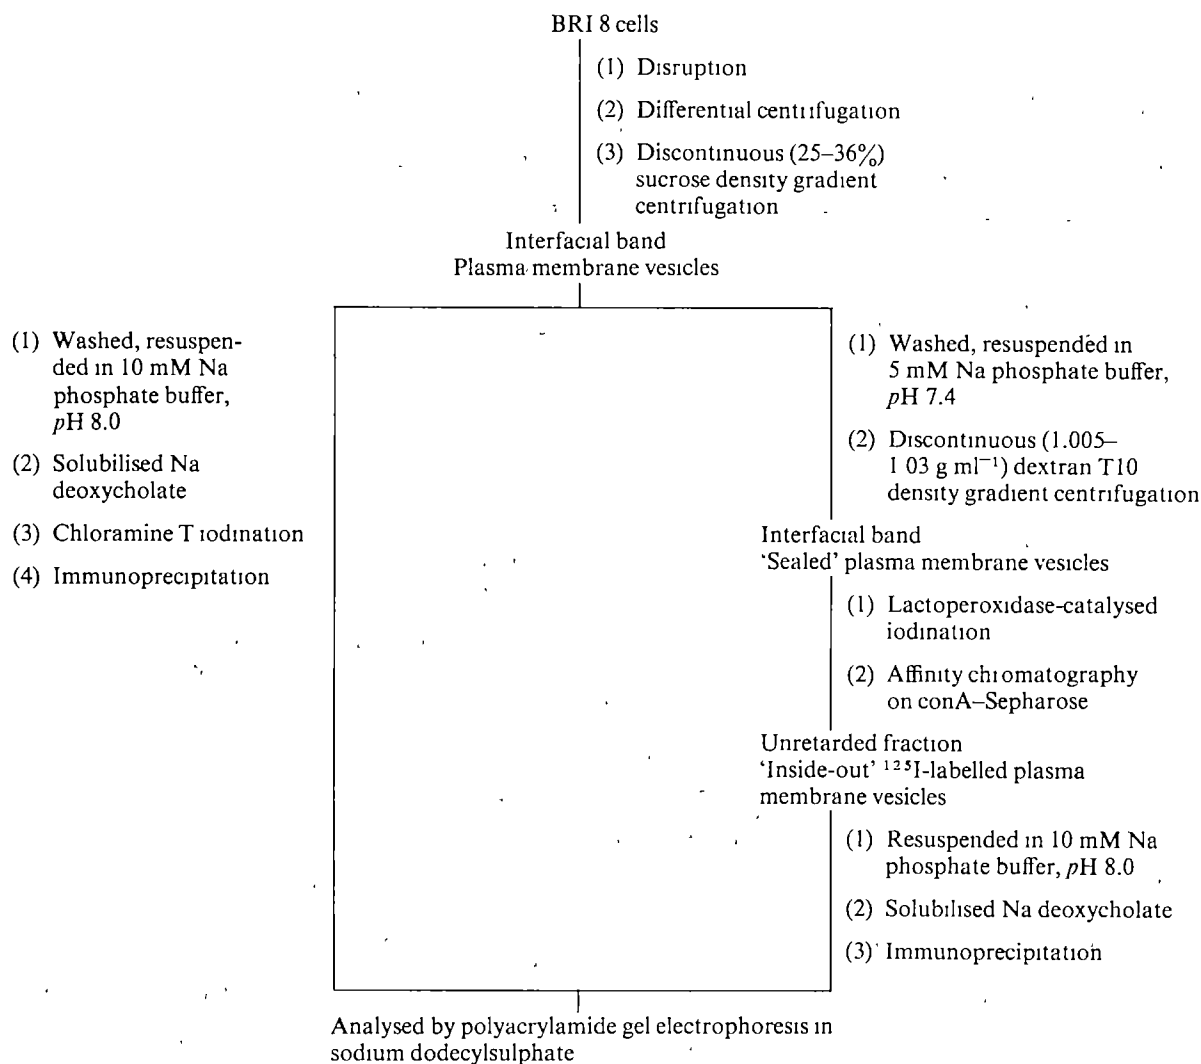

Fig. 1 Summary of experimental procedure for designating orientation of lymphocyte surface antigens. The procedure is shown for BRI 8 cells; an identical procedure was used for mouse spleen and thymus cells. The cells (about 80% viable; 5×10^7 cells ml^{-1}) were broken using the Stansted cell disruptor (model A0 612, disrupting valve 516, air pressure applied to disrupting valve was 55.2 kPa for BRI 8 and 250 kPa for mouse thymus and spleen cells). The plasma membrane fraction was separated as previously described^{19, 21, 23}, washed free of sucrose and resuspended in 5 mM Na phosphate buffer, pH 7.4. Sealed vesicles were separated by centrifugation on discontinuous gradients of Dextran T10 (Pharmacia) for 2 h at 40,000 r.p.m. in a Beckman SW41 rotor⁸. The vesicles that accumulated at the interface between 1.005 and 1.03 g ml^{-1} were impermeable to dextran of 10,000 molecular weight. This fraction represented at least 25% of BRI 8 plasma membrane but was no more than 10% of the membrane preparations from mouse spleen or thymus cells. The sealed vesicles (2–3 mg of membrane protein in 1 ml of 5 mM Na phosphate buffer, pH 7.4) were iodinated by adding 1 mCi Na^{125}I , 20 μg lactoperoxidase, 2.3 units glucose oxidase and glucose to a final concentration of 20 mM. After 15 min at 20 °C the reaction was terminated by adding 40 volumes of 5 mM Na phosphate buffer, pH 7.4, at 4 °C. The iodinated membrane was recovered by sedimentation at 75,000g for 30 min and inside-out vesicles were separated as described previously using concanavalin A–Sephrose 4B²¹. The ^{125}I -labelled inside-out membrane vesicles (about 1 mg of protein) were solubilised at 4 °C by addition of Na deoxycholate [10% (w/v) in 10 mM Tris-HCl buffer, pH 8.2] to a final concentration of 2% (w/v). After 30 min the solution was centrifuged at 100,000g for 1 h. Plasma membranes from BRI 8, mouse spleen and mouse thymus cells for control immunoprecipitations (about 1 mg of each) were solubilised in 1 ml of 2% (w/v) Na deoxycholate and non-vectorially labelled with Na^{125}I (1 mCi) by using Chloramine T (10 μg)³⁰.

basis of being inhibited completely by an authentic sample of β_2 -microglobulin, and having no detectable reactivity with erythrocytes and the lymphoblastoid cell line 'Daudi' which lack HLA-A, B and C antigens. A rabbit antiserum raised by hyperimmunisation with a glycoprotein fraction from BRI 8 plasma membrane was used to precipitate the HLA-Ia antigens—according to various criteria this antiserum recognised the human counterparts of the mouse Ia antigens^{24, 28}. Mouse thymocyte Thy-1 was precipitated by a xenogeneic cross-reacting antiserum raised against rat brain Thy-1^{25, 29} (from A. F. Williams). IgM from BRI 8 cells was precipitated by a commercial sample (Organon) of goat anti-(human IgM) serum, and mouse spleen membrane IgM and IgD were precipitated using an antiserum raised against mouse serum Ig (from M. C. Raff).

Numerous studies have shown that each of the above antigens is exposed on the cell surface. This disposition was confirmed for the cells chosen for study by using fluorescein-labelled anti-(Ig) sera to

reveal antigen-specific antibody bound to the cell surface in the fluorescence activated cell sorter. Thus, all BRI 8 cells were stained by anti-(β_2 -microglobulin), anti-(HLA-Ia) and anti-(IgM) sera relative to control cells which had not been incubated with specific antibody. Similar results were found with the anti-(Thy-1) serum on mouse thymus cells, whereas anti-(mouse Ig) serum stained about 50% of mouse spleen cells.

¹²⁵I-labelled inside-out plasma membrane vesicles

The preparation of iodinated inside-out plasma membrane vesicles from the various cell-types is summarised in Fig. 1. The initial purified plasma membrane preparation was not significantly contaminated by other subcellular fractions¹⁹. Previous results indicated that it represented a mixture of right-side-out and inside-out vesicles that were permeable to certain macromolecules²¹. Fractionation of the vesicles on a discontinuous density gradient

of dextran T10, in a manner similar to that used for preparing sealed erythrocyte vesicles⁸, yielded a population which by implication was impermeable to lactoperoxidase and which, thus, permitted vectorial labelling. The proportion of vesicles sealed to dextran T10 varied with the cell type and was not easily manipulated. Iodination of these vesicles was followed by fractionation on concanavalin A-Sepharose 4B (ref. 21) to separate the inside-out vesicles.

Fig. 2 Comparison of polypeptides labelled by lactoperoxidase-catalysed iodination of *a*, whole BRI 8 cells and *b*, inside-out plasma membrane vesicles. BRI 8 cells [10^7 in 100 μ l of phosphate buffered saline (PBS, 10 mM Na phosphate buffer 0.15 M NaCl, pH 7.4)], were iodinated by adding 300 μ Ci of Na 125 I, 20 μ g ml $^{-1}$ of lactoperoxidase, 2.3 units ml $^{-1}$ glucose oxidase and glucose to a final concentration of 20 mM. The reaction was allowed to proceed for 15 min at 20 $^{\circ}$ C and was terminated by the addition of 100 volumes of PBS. The cells were washed twice and finally resuspended in 1 ml of sodium dodecyl sulphate (SDS) sample buffer [2% (w/v) SDS, 10% (w/v) glycerol, 0.01 M dithiothreitol and 0.02% (w/v) bromophenol blue]. 125 I-labelled inside-out plasma membrane vesicles were prepared from BRI 8 cells as described in Fig. 1. They were sedimented by centrifugation at 75,000g for 30 min and resuspended in SDS sample buffer. Samples were boiled for 2 min and analysed by polyacrylamide gel electrophoresis in SDS using the Tris-glycine discontinuous buffer system of Laemmli³¹. Iodinated polypeptides were revealed by autoradiography. Molecular weights (given in thousands) were calculated by reference to the mobilities of standard proteins: myosin (200), β -galactosidase (130), phosphorylase (90), transferrin (78), bovine serum albumin (67), ovalbumin (46), Ig L-chain (25) and cytochrome C (12.5).

Figure 2 shows representative patterns of the iodinated polypeptides of 125 I-labelled whole BRI 8 cells (the outer surface) and of 125 I-labelled inside-out plasma membrane vesicles (the inner surface), as revealed by polyacrylamide gel electrophoresis in sodium dodecylsulphate. The clear differences between the patterns inspires confidence in the efficacy of the overall procedure. The samples contained more than 10 co-migrating polypeptides which on the basis of this criterion have a transmembrane orientation. Similar results have been obtained for pig lymphocytes²² as well as mouse thymus and spleen cells.

Immunoprecipitations

Immunoprecipitation analysis of the 125 I-labelled inside-out vesicles after solubilisation in sodium deoxycholate was undertaken to determine whether any of the inner-surface iodinated polypeptide chains could be equated with known cell surface antigens. A positive result would indicate that the antigen in question was exposed on both faces of the lipid bilayer and was, thus, a transmembrane protein. Each of the cell surface antigens chosen for study was also shown to be a component of the purified plasma membrane by immunoprecipitation from solubilised membrane that had been labelled non-vectorially by iodination using Chloramine T³⁰. The results for the various antigens are summarised in Fig. 3.

The HLA-A, B and C gene products are glycosylated polypeptides of 43,000 molecular weight²³. Immunoprecipitation of the 125 I-labelled inside-out membrane vesicles with the anti- β_2 -microglobulin serum gave one band only of molecular weight 43,000 (Fig. 3*b*), whose position was identical with that of the band of the control precipitate from the non-vectorially iodinated plasma membrane (Fig. 3*a*). If lactoperoxidase-catalysed iodination of the inside-out vesicles labels exposed tyrosine residues on the inner membrane surface only, then this result indicates that the HLA-A, B and C polypeptides span the lipid bilayer. The β_2 -microglobulin component of the HLA-A, B and C antigens was not detected because at the polyacrylamide gel concentration used (7.5%) β_2 -microglobulin was not resolved from the dye front and was run off the gel together with the radioactive iodide.

Similar results were obtained for the HLA-Ia antigens. These antigens comprise two non-covalently associated glycosylated polypeptides of 28,000 and 33,000 molecular weight²⁴. Figure 3*c* shows that the plasma membrane contained both polypeptides and Fig. 3*d* indicates that both are exposed on the inner membrane surface.

In contrast, neither the μ nor L chains of human IgM were labelled in the inside-out vesicles (Fig. 3*f*), although Fig. 3*e* indicates that the plasma membrane contained IgM and that both chains were iodinated when the Chloramine-T procedure was used. An identical result was obtained for mouse spleen cell Ig. Thus, the μ , δ and L chains were present in the plasma membrane (Fig. 3*g*), but were not labelled in the inside-out membrane vesicles (Fig. 3*h*). Similarly, Thy-1 antigen (molecular weight about 25,000³³) was a component of the thymus plasma membrane (Fig. 3*i*), but was not labelled in the inside-out vesicles (Fig. 3*j*).

Conclusions

The significance of the results depends on the subpopulation of plasma membrane vesicles used for the labelling studies being correctly designated as inside-out and sealed to lactoperoxidase. This designation is supported by two experiments. First, the failure to label certain known membrane components by lactoperoxidase-catalysed iodination (Fig. 3) argues strongly against the vesicles being leaky to lactoperoxidase. Second, the different labelling patterns given by intact cells and by the membrane vesicles (Fig. 2) argues that the outer surfaces of the cells and membrane vesicles possess different structures which is consistent with a different orientation. If these interpretations are correct then the prescribed method is applicable to the identification of lymphocyte transmembrane proteins as well as providing the means to probe the structure of the plasma membrane's inner surface. It seems likely that the approach will be generally applicable to a variety of cell types, especially since inversion of plasma orientation may be a general feature of cell breakage³⁴.

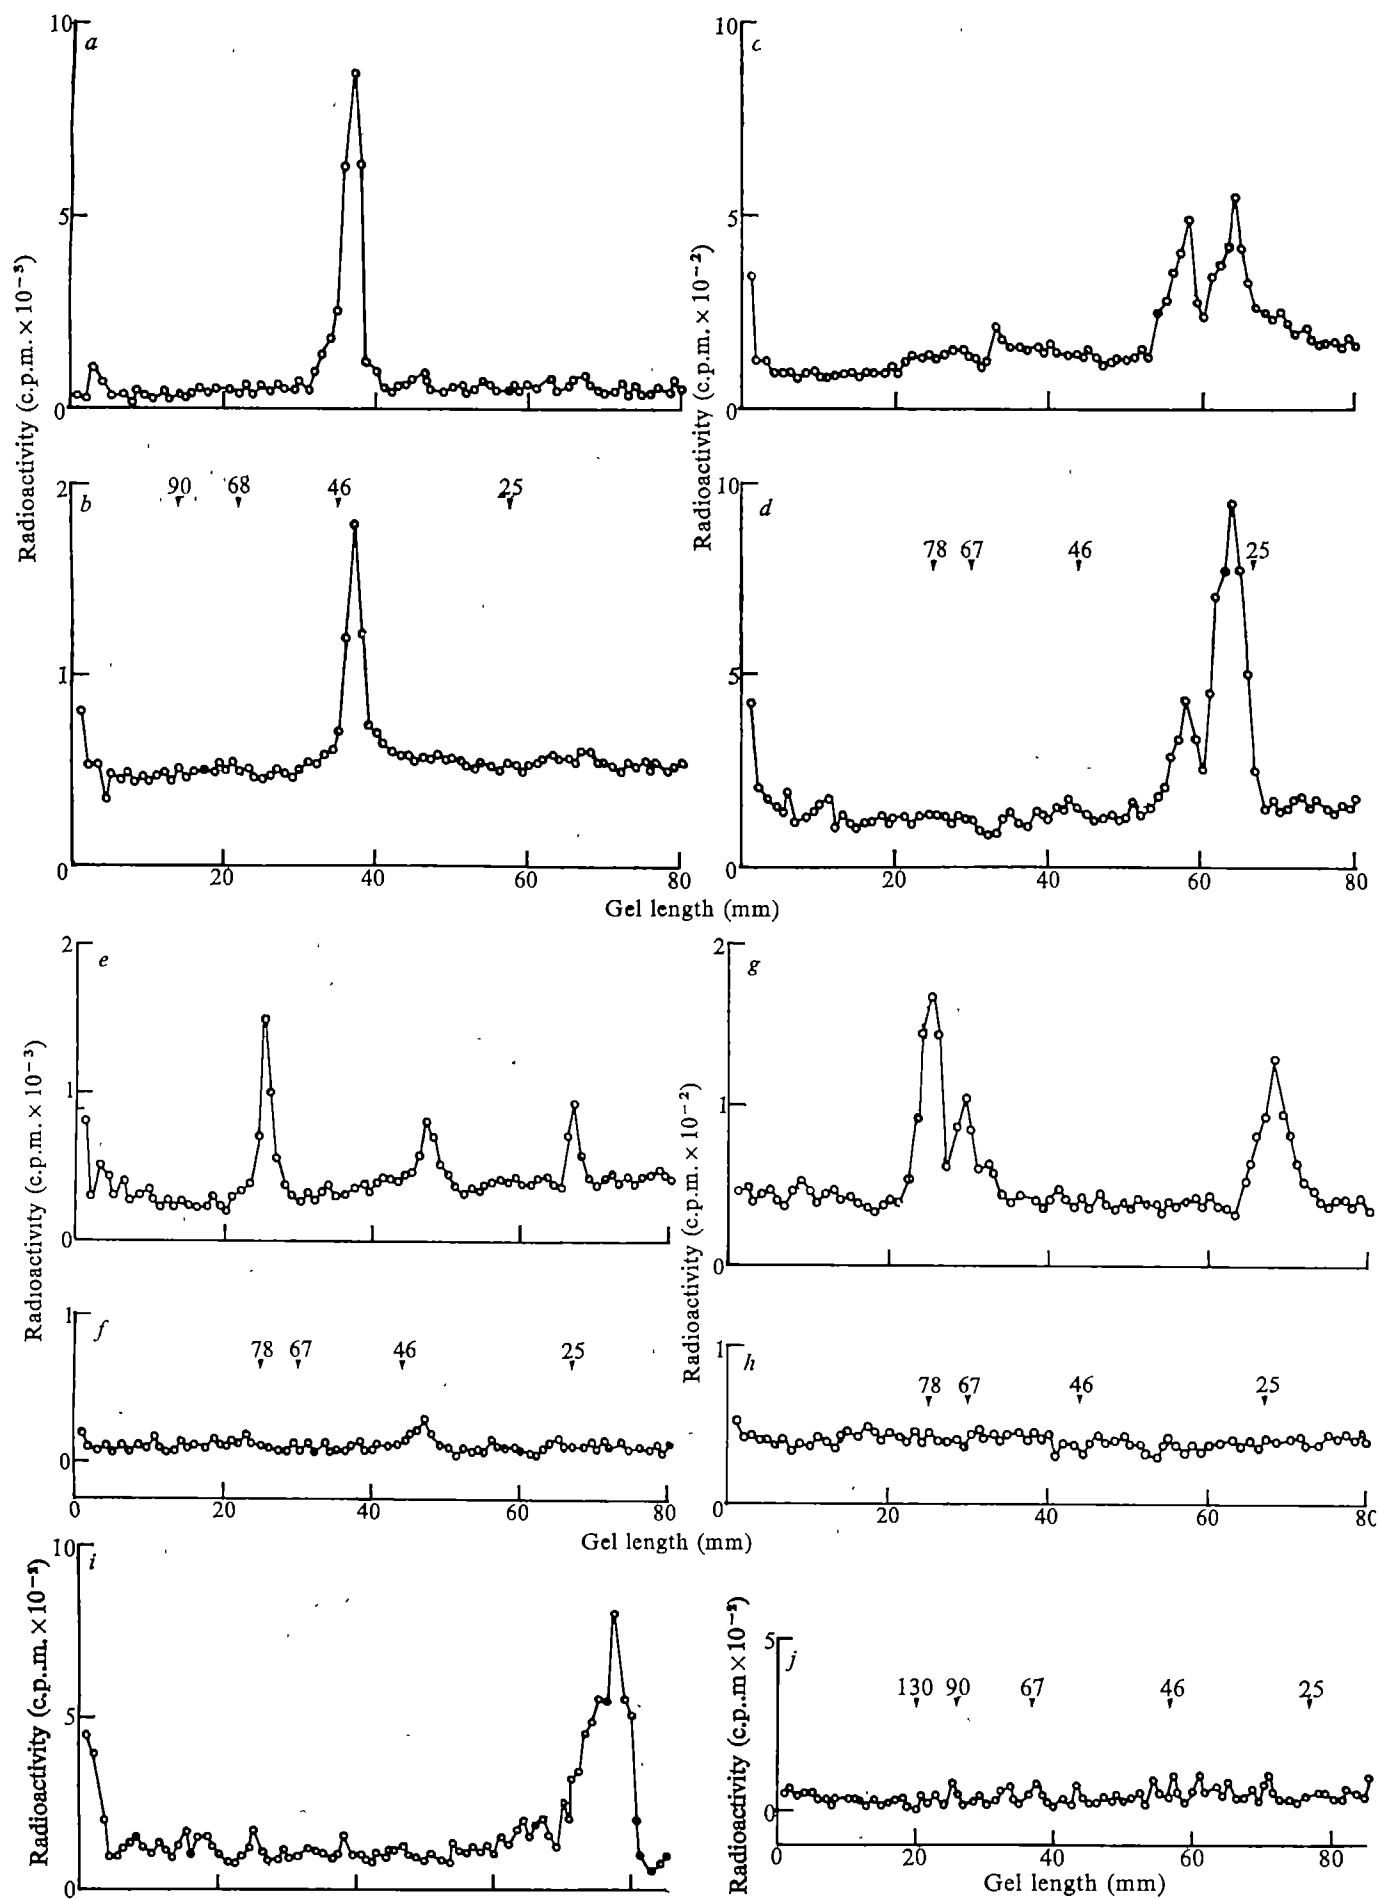

Fig. 3 For description see opposite

Fig. 3 Polyacrylamide gel electrophoresis patterns in SDS of immunoprecipitates prepared from ^{125}I -labelled inside-out membrane vesicles with *b*, anti-(human β_2 -microglobulin); *d*, anti-(HLA-Ia); *f*, anti-(human IgM); *h*, anti-(mouse Ig) and *j*, anti-(Thy-1) sera. These patterns should be compared with those obtained from the non-vectorially iodinated plasma membrane with *a*, anti-(β_2 -microglobulin); *c*, anti-(HLA-Ia); *e*, anti-(human IgM); *g*, anti-(mouse Ig) and *i*, anti-(Thy-1) sera. The preparation of ^{125}I -labelled inside-out membrane vesicles and ^{125}I -labelled plasma membrane is described in Fig. 1. Three methods of immunoprecipitation were used depending on the quantity of antiserum available. First, the Ig fractions of the anti-(β_2 -microglobulin), anti-(HLA-Ia), anti-(mouse Ig) and normal rabbit serum were coupled to cyanogen bromide activated Sepharose CL-4B at a concentration of 10 mg of protein per ml of gel sediment. Before interaction with specific antibody the deoxycholate-solubilised ^{125}I -labelled membranes (Fig. 1) were depleted of non-specifically bound protein by incubation for 30 min at 20°C on a 5 ml column of normal rabbit Ig-Sepharose CL-4B. Unadsorbed protein was eluted with 0.5% (w/v) Na deoxycholate. The eluate was incubated for 30 min at 20°C on 5 ml columns of immune Ig-Sepharose CL-4B that were subsequently washed with 0.5% (w/v) Na deoxycholate. The adsorbed material was eluted with 2% (w/v) SDS in 8 M urea, precipitated with ethanol (final concentration 66%) for 48 h at -20°C , solubilised in SDS sample buffer and analysed by polyacrylamide gel electrophoresis in SDS as described above. After electrophoresis and staining with Coomassie blue the gels were dried, divided into 1 mm slices and counted in a Packard gamma counter. Second, *Staphylococcus aureus* A protein attached to Sepharose CL-4B was used as the absorbent for the anti-(human IgM) serum. The protein prepared as previously described³² was coupled to Sepharose CL-4B (1 mg of protein per ml of gel sediment). The deoxycholate-solubilised ^{125}I -labelled BRI 8 membranes were pre-adsorbed with normal rabbit Ig-Sepharose CL-4B as described above. The eluate was incubated at 37°C with 100 μl of anti-(human IgM) serum for 1 h followed by 12 h at 4°C and then incubated for 30 min at 20°C with the *Staph* A-Sepharose CL-4B. Unadsorbed material was eluted with 0.5% (w/v) Na deoxycholate. The bound material was displaced with 2% (w/v) SDS in 8 M urea and treated as previously described. Third, a direct precipitation system was used for the mouse thymus Thy-1 antigen. Deoxycholate-solubilised ^{125}I -labelled membrane (300 μl) was incubated at 37°C for 30 min with 30 μl of anti-(Thy-1) serum, for a similar period with 50 μl of horse anti-(rabbit Ig) and then cooled to 4°C for 12 h. The resulting precipitate was washed four times with 0.5% (w/v) Na deoxycholate at 4°C , solubilised in 2% (w/v) SDS in 8 M urea and analysed as above.

The major limitation of the method concerns the selectivity of iodination which is restricted to exposed tyrosine residues. As a result, lack of labelling may reflect lack of an accessible tyrosine residue rather than absence of the polypeptide chain *per se*.

The plasma membrane of the human B-lymphoblastoid cell line BRI 8 contained at least 10 transmembrane proteins as assessed by the comigration of polypeptide chains which were iodinated on both the outer surface of intact cells and of inside-out membrane vesicles (Fig. 2). Similar results have been obtained with pig lymphocytes²². In this case the majority of the transmembrane proteins were further identified as glycoproteins on the basis of specific adsorption to *Lens culinaris* lectin-Sepharose²². A preferential disposition of glycoproteins to a transmembrane orientation is in accord with models of plasma membrane structure based on erythrocytes^{12,13}.

Direct evidence was obtained that the polymorphic, 43,000 molecular weight polypeptide chain of the HLA-A, B and C antigens spans the lipid bilayer. This conclusion is in accord with the orientation suggested previously on the basis of the amino acid composition of enzymatic cleavage products³⁵. It is also concluded that both of the polypeptides (28,000 and 33,000 molecular weight) which comprise the HLA-Ia antigens are transmembrane.

The significance of the lack of labelling of Thy-1 antigen and membrane-bound Ig in the inside-out vesicles is equivocal because of the selectivity of the labelling procedure. Other arguments may, however, be invoked in favour of the view that the lack of labelling of IgM is a true reflection of its orientation. Thus, membrane-bound IgM binds very much less detergent than typical integral membrane proteins including Thy-1 and HLA-A, B and C and Ia antigens^{24,33,36}. This difference in behaviour is consistent with the proposal that IgM dips much less extensively into the bilayer than known transmembrane proteins. Also, if the μ -chain of membrane-bound IgM spans the membrane it should be iodi-

nated, assuming its structure is identical with that of secreted IgM which has tyrosine as its C-terminal amino acid residue³⁷.

We thank Drs M. C. Raff and A. F. Williams for gifts of antisera, and Dr A. J. Edwards for examining the cell suspensions for surface antigens in the fluorescence activated cell sorter.

letters to nature

Possible fast variability of the nucleus of Cen A at 13.5 mm

INFORMATION about short time scale events in extragalactic objects can have very important implications for the theoretical interpretation of the physical mechanisms involved. Such data are only obtained by using time-consuming observing schedules and methods, and are not

usually carried out at radio observatories. This kind of information is thus generally lacking. We report here a study of the nucleus of Cen A (NGC 5128) at a wavelength of 13.5 mm. Possible fast variability was observed.

Observations in the direction of the infrared 'hot-spot' of NGC 5128 (ref. 1) have been made at centimetre and millimetre wavelengths²⁻⁴. Kellermann⁵ has suggested an important intraday change of flux, based on few observations taken at 3.4 and 9.5 mm. Fogarty and Schuch⁶ found no variability using observations obtained monthly at

13.5 mm, in 1974. X-ray emission from the nucleus of NGC 5128 was identified by Tucker *et al.*⁵, and important variability has been claimed by other workers at X-ray wavelengths^{6,7}.

We performed 37 observations of the nucleus of NGC 5128 at $\lambda=13.5$ mm from July 1976 to March 1977, which included two periods of 15 d sequential patrol (26 July to 10 August, and 27 November to 13 December, in 1976). The observations were carried out using a 45-foot dish at Itapetinga Radio Observatory, Atibaia, Brazil. All observations were performed at the same sidereal time at the local meridian transit to avoid polarisation effects. The antenna beam at 13.5 mm is of about 4' arc, and observations were made using on-on and beamswitching techniques.

For comparison we observed Vir A in sequence, as a calibrator (for which we adopted 21.4 Jy). After 10 November 1976 we also observed the NE lobe of NGC 5128 (13 h 42 min 48 s, $-42^\circ 42' 11''$, 1950.0 coordinates). This position is situated nearly 2.5' arc NE of the nucleus such that there was only a weak beam overlap with less than about 3 dB of attenuation. This lobe was selected for comparison since close to it, in NE direction, it has been recently found some H II filamentary structures (ref. 8 and M. Dennefeld, personal communication). It corresponds to a structure identified at decimetric and metric wavelengths⁹⁻¹¹.

The measurements were normalised against Virgo A and are shown in Fig. 1. Nearly all observations were carried in the following sequence of 30 min integrations: Vir A, NE lobe, centre, Vir A. In some days the integration times were extended with 15 min extra observations. Sky attenuation was measured before and after the sequence, and the average was adopted for data correction. The error bars are $\pm 1\sigma$ referred to the worst 30-min integration measurement of the sequence. Larger error bars refer to days with bad weather, and the measurements are consequently less

reliable. In general both atmospheric and instrumental changes affected similarly all observations from a sequence.

Figure 1 suggest an 'event' (with flux reduction) in 22 November–5 December 1976, in the centre/Vir A and centre/NE lobe series of observations. This is not suggested in the NE lobe/Vir A series. Both centre/Vir A and NE lobe/Vir A data show reduced values in 11–12 November 76 and 10–11 March 77—and this is not seen in centre/NE lobe data.

It should be stressed that the observations of the centre and NE lobe were performed in nearly equal conditions, using the same corrections (elevation angle of about 70°). Vir A was observed in the opposite hemisphere at a lower elevation angle (about 45°), and the measurements suffered different corrections. An error in the estimate of the sky attenuation will not affect the relative measurement centre/NE lobe, but may affect Vir A corrected measurements, and thus centre/Vir A and NE lobe/Vir A comparisons. Thus the centre/NE lobe data are the most reliable for comparison purposes.

The coincidence in the 'event' occurrence both in the more reliable comparison centre/NE lobe and in centre/Vir A suggests that it might be of a real nature. On the other hand, due to the reasons discussed above, the reduction in centre/Vir A and NE lobe/Vir A in November 76 and March 77 could not be attributed necessarily to changes in Vir A.

The possible 'event' described here is relatively much better defined than Kellerman's² 2 d data at 3.4 mm, which have also shown a flux reduction of nearly 30%. This reduction alone bring some complications for the interpretation. But we feel the data are still few, and the effect might be only a part of a larger more complex event.

Long term data seem to confirm that there are no large time scale variations in flux from the nucleus of Cen A

Fig. 1 Observations at 13.5 mm of the nucleus of Cen A in relation to Virgo A (a), of the nucleus of Cen A in relation to NE Lobe of Cen A (b), and of NE Lobe of Cen A in relation to Vir A (c). Ordinates are in relative units. Error bars correspond to standard errors of the mean.

(ref. 4). Short time scale events might happen within a few days, however. Complete description of the pattern will require daily observations over several months.

It should be noted that the previous map¹² of NGC5128 was derived with isotherms referred to the centre, for which variability was not taken into account. An improved version of the map at 13.5 mm is under investigation.

We thank Drs K. J. Kellermann, J. Beall and M. Dennefeld for useful discussions. This work was supported in part by Brazilian research agencies CNPq and FAPESP.

Pi 1-2 magnetic field pulsations on dayside cleft field lines

TYPE Pi 1-2 magnetic field pulsations, $T = 1-150$ s, have a broad-band, noise-like character and a tendency to occur during active aurorae and magnetospheric substorms^{1,2}. It is well-known that type Pi 1-2 magnetic field pulsations observed in the night-morning sector during magnetospheric substorms maximise in amplitudes along the auroral oval^{1,2}. But the relation of the Pi 1-2 activity to the day sector of the auroral oval has not been clear. This relation is of particular interest because the day sector of the auroral oval seems to coincide approximately with the feet of the dayside cleft field lines; the precise relation between the dayside cleft and the dayside auroral oval, however, has not yet been established (S. I. Akasofu, personal communication). Dayside cleft field lines usually terminate between the geomagnetic latitudes of 75° and 80°. We show here that intense Pi 1-2 activity appeared at College on two occasions when the cleft came down to the College latitude, 64.7° N, at times when College was in the midday sector. Further, it is shown that an intense flux of particle precipitation into the dayside ionosphere occurred on the second occasion, 4 August 1972.

A direct comparison between Pi 1-2 activity as observed at Bar I (70.3°N, 257°E, geom.) and College (64.7°N, 257°E) on 26-27 July 1969, and observations of the dayside cleft by satellite³ is shown in Fig. 1. In the interval 2000-0100 UT, which is local midday at Bar I and College, the cleft moved towards the equator, approaching 66° at 0100 UT. Pi 1-2 activity was most intense at Bar I between 2300 and 0100 UT when Bar I was on cleft lines. Pi 1-2 was most prominent at College between 0100 and 0200 UT, but was not as intense as at Bar I (maximum amplitudes near 0.02 Hz were 16 nT at Bar I and 6 nT at College). This behaviour is consistent with a Pi 1-2 origin on cleft lines.

The cleft tends to move to smaller L values ($L = \text{McIlwain's parameter}$; the invariant latitude ($\Lambda_0 = \cos^{-1} (1/L)^{1/2}$), with increasing values of the AE index³. From this, we would expect Pi

activity to be seen at College in midday hours preferentially at times of high AE (or Kp) if the midday Pi 1-2 activity does maximise on cleft lines. To check this, we looked at College Pi data^{4,5} and found that Pi occurred in midday hours at College on about 30 d in 1966 and 1967 with Kp values ranging from 4 to 9. In contrast, Pi activity is prominent at College in night hours for Kp from 2 to 5. These characteristics seem consistent with a Pi oval that coincides approximately with the cleft lines on the day side.

On 4 August 1972, at 2240 UT, the magnetopause moved inward past Explorer 45, then at $L = 5.2$ and at 1435 MLT⁶.

Fig. 1 Appearance of type Pi 1-2 pulsations at *b*, Bar I and *c*, College 2300-0200 UT when dayside cleft lines were in the vicinity of those sites. *a*, from Yasuhara and Akasofu ref. 3.

An induction magnetometer operating near Chatanika, $L = 5.6$, 40 km north of College, registered very strong Pi 1-2 activity at that time. The activity actually exceeded the record range of the tape recorder (30 nT at 0.02 Hz). Sonograms show that the pulsations had the broad-band form that characterises Pi 1-2 activity. The Kp index was 9₀ at the time and AE reached 2065 nT.

Since the magnetopause moved inwards past $L = 5.2$ at 2240 UT, it evidently passed $L = 5.6$ somewhat earlier, hence Chatanika was on cleft lines for the duration of the strong Pi activity observed there. Direct Chatanika radar observations showed the cleft to be located near Chatanika from 2200-2300 UT on 4 August⁷.

The Chatanika radar⁸ was in operation at the time, and the data show that prominent *E*- and *D*-regions were formed⁹ (Fig. 2). The College 30 MHz riometer went off scale in this interval, the absorption exceeding 20 dB (ref. 11). These measurements show conclusively that a field-aligned plasma stream was present on the dayside cleft field lines. Using Chatanika radar electron densities and appropriate auroral ionosphere *D*-region collision frequencies, the absorption at Chatanika was estimated to be 21.4 dB at 30 MHz, which could be produced by 70 keV electrons with a minimum precipitation rate of 3×10^6 e cm⁻³ s⁻¹ ster⁻¹ (ref. 10). Similar estimates of precipitating particle energies during this period have been given by other investigators¹².

Fig. 2 Chatanika radar electron density data for 4 August 1972. Densities of up to $5 \times 10^5 \text{ cm}^{-3}$ were observed at the feet of dayside cleft field lines 2200–2300 UT (from Watkins *et al.*, ref. 7).

Since an intense field-aligned flux of electrons was present on the field lines where the Pi 1–2 pulsations were observed, it is possible to invoke the garden-hose overstability mechanism for the generation of the Pi 1–2. The garden-hose overstability is a consequence of field-aligned plasma streaming in the presence of magnetic mirroring, conditions that are met in the magnetosphere¹³. The plasma pressure becomes anisotropic with $P_{\parallel} > P_{\perp}$, the anisotropy increasing with increasing streaming speed, and this anisotropy generates Alfvén waves⁹. Thus particle energies of 1–100 keV are favourable for the generation of the unstable Alfvén waves through the garden-hose mechanism, and those energies were observed in the cleft region in the case of the 4 August 1972 activity⁶.

Observations of strong Pi 1–2 activity in the day sector may be useful for locating cleft field lines in experiments where supplementary knowledge of the cleft location is required. In recent years, the most usual ground-based technique for locating the cleft field lines in the ionosphere has been the ionosonde technique. Since magnetometer data are considerably easier to obtain than ionosonde, particularly on a continuous long-term basis, it is advisable to extend the present investigation to Pi 1–2 recording sites between 70° and 80°.

Linear dichroism probes to study internal electric fields

LARGE electric fields outside a highly charged macro-ion or between any ion and its counter ion atmosphere form the basis of electrolyte theory. The fields manifest themselves in a number of macroscopic properties of such systems, but few, if any, successful measurements of such fields have been possible. We report here observations which suggest that optical probes can be used as field meters in anisotropic solvents: In aqueous solutions containing flow-aligned cylindrical micelles of cetyltrimethylammonium bromide (CTAB) several anisotropic anions exhibit linear dichroism effects which can be ascribed to orientation and perturbation of these chromophores by a radially directed field of about 10^8 V m^{-1} surrounding each $(\text{CTA}^+)_n$ cylinder.

Linear dichroism ($\text{LD} = A_{\parallel} - A_{\perp}$, definition and measuring techniques in refs 1–3) and absorption (A) spectra were recorded on several substances, added in small amounts (maximum 0.1%), in aqueous CTAB (20%) solution, in a Couette device at radial optical propagation. At the concentration and temperature used, this detergent forms practically infinite cylindrical micelles, with a diameter of $\sim 50 \text{ \AA}$, which are alignable in a flow gradient^{3,4}. The observation of a non-zero LD (Table 1) is not *a priori* unequivocal evidence for an interaction between the chromophore and the fields around the macro-ion, but one has first to correct for the so-called Wiener dichroism ($= \text{WLD}$, defined in ref. 5) which is the imaginary correspondence of form-birefringence. WLD has the shape of the absorption spectrum (WLD/A being constant), but its sign depends on the dielectric constant of the medium surrounding the chromophore. In micellar CTAB, WLD is positive for chromophores close to the cationic micelles and negative for peripherally located chromophores. Thus anions have positive, and cations negative WLD⁵. The observed LD was corrected for the expected WLD (Table 1). For ions like $\text{Cr}(\text{oxalate})_3^{3-}$ or other pseudo-cubic ions⁵, WLD is sufficient to explain the observed signals. This is also true for anisotropic cations, which by avoiding the macro-ion are in regions with comparatively weak electrostatic fields. With anisotropic anions the situation is different and after eliminating WLD, a sometimes complicated pattern of bands of any sign remains (Table 1, Fig. 1).

From the treatments of Labhart⁶, Liptay⁷ and Lin⁸ on molecules in electric fields, one has for the absorption difference $A_{\chi} - A$, due to an electric dipole allowed transition $b \leftarrow a$, at the frequency ω (A_{χ} is the absorption with an angle χ between the electric field and the electric vector of the polarised light; A is the absorption in the absence of field):

$$\text{ELD}\chi(\omega) = (A_{\chi} - A)\omega = \frac{\beta E^2}{10} A(\omega) S + \frac{\omega E^2}{10\hbar} \frac{\partial}{\partial \omega} \left\{ \frac{A(\omega)}{\omega} \right\} T + \frac{\omega E^2}{10\hbar^2} \frac{\partial^2}{\partial \omega^2} \left\{ \frac{A(\omega)}{\omega} \right\} U \quad (1)$$

$$\text{where } S = (3 \cos^2 \chi - 1) [(\hat{p}_{ab} \cdot \alpha(a) \cdot \hat{p}_{ab} - \frac{1}{3} T_r(\alpha(a))) + \beta((\hat{p}_{ab} \cdot p_{aa})^2 - \frac{1}{3} |p_{aa}|^2)]$$

$$T = [(2 - \cos^2 \chi) T_r(\Delta \alpha(b, a)) + (3 \cos^2 \chi - 1) \hat{p}_{ab} \cdot \Delta \alpha(b, a) \cdot \hat{p}_{ab} + 2\beta[(2 - \cos^2 \chi) p_{aa} \cdot \Delta p(b, a) + (3 \cos^2 \chi - 1) (\hat{p}_{ab} \cdot p_{aa}) \hat{p}_{ab} \cdot \Delta p(b, a)]]$$

$$U = [(2 - \cos^2 \chi) |\Delta p(b, a)|^2 + (3 \cos^2 \chi - 1) |\hat{p}_{ab} \cdot \Delta p(b, a)|^2]$$

where $\beta = 1/kT$, \hat{p}_{ab} is a unit vector along the transition moment p_{ab} ; $\alpha(a)$ and $p_{aa} = \sum e r_i$ are the polarisability tensor and the permanent dipole moment, respectively, of the ground state. $\Delta \alpha(b, a)$ and $\Delta p(b, a)$ are the difference in polarisability and the difference in dipole moment, respectively, between the ground and the excited states. If dipole orientation effects⁹ predominate over

effects due to electronic perturbations (that is, T , U and $\alpha(a)$ can be neglected) we have

$$\frac{A_{\parallel} - A_{\perp}}{A} = \frac{A_{\parallel=0} - A_{\parallel=\pi/2}}{A} = \frac{1}{10} \left(\frac{|p_{aa}| |E|}{kT} \right)^2 (3 \cos^2 \theta - 1) \quad (2)$$

where θ is the angle between p_{ab} and p_{aa} . After scaling by $-1/2$ equation (2) applies to the geometry of the CTAB system (\parallel = the direction of the micelle cylinders). In Table 1, θ values are given when \hat{p}_{ab} is available from spectroscopic assignments and p_{aa} from geometrical considerations. For an ion the dipole moment is referred to the centre of mass as origin. A generally poor agreement indicates that the assumptions behind equation (2) are not justified here. But, we get an accurate order of magnitude of the field (or at least the minimum field) since the field appears as a squared term. Thus $(A_{\parallel} - A_{\perp})/A = +0.03 \pm 0.01$ is consistent with $pE/kT = 0.39 \pm 0.06$ for a polar molecule with $\theta = 0$. If the permanent dipole moment is 5 D, which is reasonable for *p*-aminobenzenesulphonate at a neutral pH, we get $E = 2.5 \times 10^8 \text{ V m}^{-1}$ ($\pm 20\%$).

A more satisfactory treatment should rest on a semi-empirical evaluation of S , T and U by electric dichroism spectroscopy. In Fig. 2 we show the $A_{\parallel=\pi/2} - A$ spectrum of methyl red in the presence of an applied external electric field. As predicted by equation (1) the signal was found to be proportional to E^2 . The contribution from the T , 'polarisability', term is predominant and a curve with the shape of $\partial A/\partial \omega$ is obtained. Returning to the spectrum of methyl red at the surface of (CTA⁺)_n micelles (Fig. 1), we may now rationalise it, with the aid of the 'artificial' spectrum, in terms of an electrostatic field, radially directed from the (CTA⁺)_n, and with a strength of $1.45 \times 10^8 \text{ V m}^{-1}$. A higher value results if the incomplete alignment of the micelles is taken into account.

The present findings also agree with the field expected from electrostatic theory. We assume that the observed phenomena take place for ions at a distance r from the charged surface of the macroion (r being less than the thickness of the ionic atmosphere). From

the difference in potential between bound and free counterions one may approximate the field as¹⁰

$$E = \frac{l \ln(R/r) \gamma e}{r d \epsilon} \quad (3)$$

where γ is the apparent degree of dissociation of counterions, R is the apparent radius of the macromolecule and r the radius of its free volume, d the average distance between neighbouring ionised groups and ϵ the dielectric constant of the solvent (water). In the present system we take $\gamma \leq 0.5$, $R/r = 0.2$ and $d = 5 \times 10^{-10} \text{ m}$, so in the region 5–10 Å from the cylinder we have fields ranging between 8×10^8 and $4 \times 10^8 \text{ V m}^{-1}$.

Platt¹³ suggested the term electrochromism to designate all changes in optical absorption or emission of molecules in condensed phases due to external electric fields, thus including energy

Fig. 1 Linear dichroism $LD = A_{\parallel} - A_{\perp}$ and absorption (A) of methyl red in 20% CTAB, 80% H₂O at a Couette flow of $G = 2,600 \text{ s}^{-1}$ (▽) and $5,000 \text{ s}^{-1}$ (○). Optical path-length: 0.10 cm.

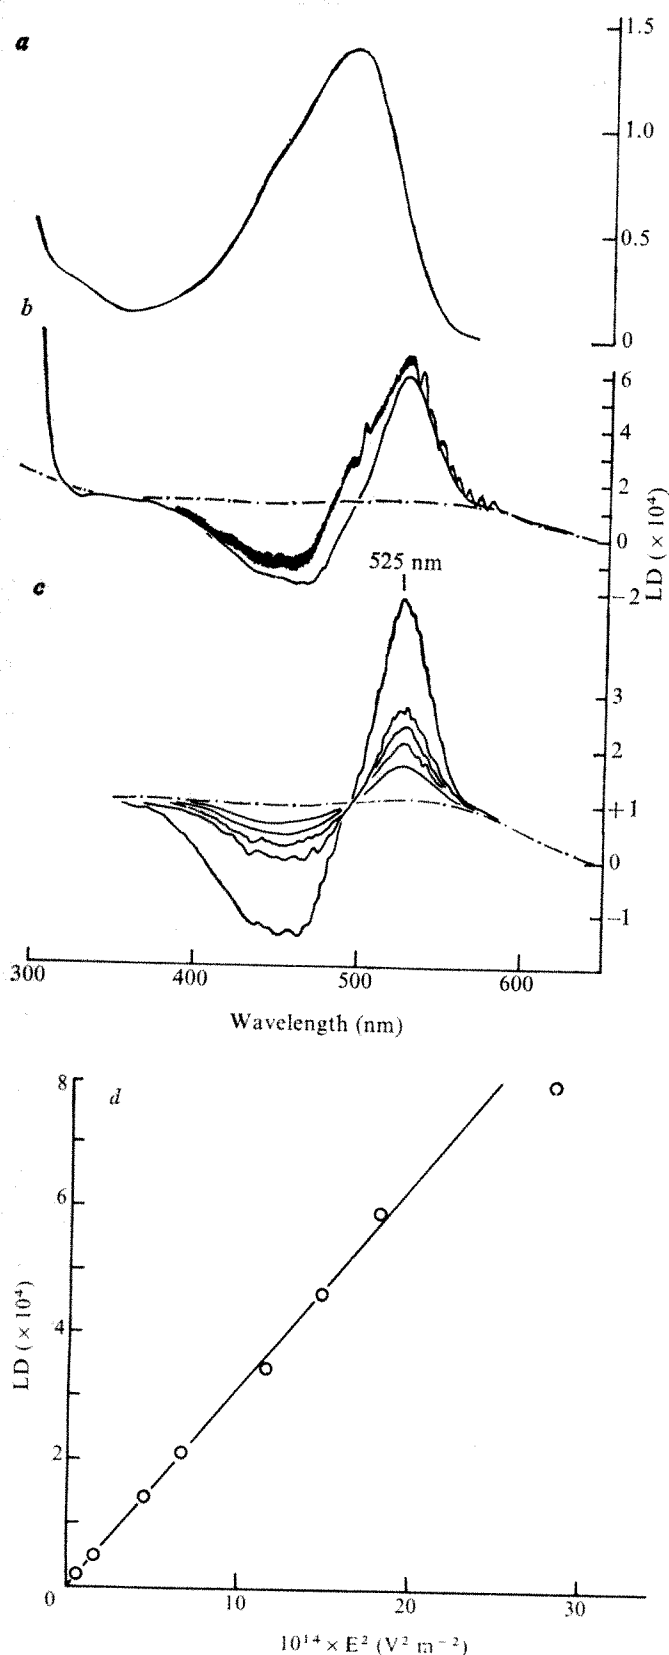

Fig. 2 *a*, Ψ Absorption and, *b*–*c*, electric linear dichroism (ELD = $A_{\lambda} - \pi/2 - A$) of methyl red in polystyrene sheet (thickness 0.0065 cm) obtained as the absorption difference with and without a longitudinal electric field (a field sinusoidally oscillating at 470 Hz between 0 and a given amplitude value, limited by flash-over around 4,000 V, was used together with lock-in electronics). *c*, Curves recorded immediately after applying the field (no orientation) at 0 (—), 1.6, 2.0, 2.3, 2.5 and 3.8×10^7 V m $^{-1}$ (certain orientation) at two spectral band widths: 2 nm (noisy curve) and 8 nm. Fringes due to interference in film, visible in the former spectrum. *d*, Steady state ELD signal at 525 nm, from the sample in *ac* plotted versus E^2 .

shifts as well as anisotropic phenomena (Kerr effect, electric dichroism). Much interest has recently centred around the internal fields in biomembranes¹⁴, solid polymers¹⁵ and so on, and the use of dye¹⁶ probes to study isotropic manifestations, such as shifts and intensity changes, of the solvent field has also been discussed. Here we report the possibility of discriminating the field effects by using anisotropic 'solvatochromism'.

Quasi-Fermi level measurement in an illuminated GaP photoelectrolysis cell

No experimental procedure is known for measuring directly the position of the minority carrier quasi-Fermi level, ϕ , at the surface of a semiconductor electrode¹. ϕ is an important parameter in studies of photoelectrolysis (p.e.) (ref. 2), of surface states, of catalysis, of the anomalous intensity dependence of the photovoltage of Schottky barriers³, and of the efficiency and stability against corrosion of low-cost photoelectrochemical solar cells. Hence a means for determining ϕ should be of wide interest. I describe here a technique which results from an effort to measure changes in the potential versus standard calomel electrode (SCE), V_{Au} , of a thin porous Type B gold film⁴ evaporated on the surface of n-GaP in a $\langle Au/GaP/K_2SO_4/Pt \rangle$ p.e. cell when the cell is illuminated with photons having energy $h\nu \geq E_G$, the 2.23 eV energy gap of GaP. Changes in V_{Au} of $\sim +1.0$ V have been observed. It is shown below that $V_{Au} \sim \phi$, the minority hole quasi-Fermi level in the illuminated n-GaP anode. This series of measurements provides other valuable information. The valence band (VB) of the Au/GaP anode is shown to > 0.21 V below, or anodic to, the OH^-/H_2O redox potential, so that oxidation of OH^- is possible. But, p.e. with liberation of H_2 and O_2 is shown to be highly improbable. The results provide evidence that the Type B gold film does not protect the GaP surface against electrochemical corrosion. The variation with time of V_{Au} provides a sensitive indicator of the existence and rate of GaP corrosion. The technique for determining ϕ should be applicable to semiconductors, both n- and p-type, other than GaP.

The single crystal n-GaP (Metals Research) anode was prepared with a sintered Au + 12%Ge alloy ohmic contact on the rear surface and the front surface was etched in aqua regia. A ring of electrically insulating Sealit (Fisher Scientific) 1 mm wide was painted on the front surface at its perimeter, leaving a clear area in the centre. A 16 nm thick Au film was rapidly evaporated (3 s) to cover both the Sealit ring and the clear area. Electrical

contact to the Au film was by means of a Au-foil ring placed between the gold-covered Sealit and the polyethylene cell wall, which had a 0.6-cm diameter hole through which illumination reached the 0.12-cm² exposed Au surface.

A schematic view of the cell and electrical connections is given in Fig. 1. Illumination intensity L approximates 2 am1 suns ≈ 150 mW cm⁻². Potentials were measured between the Au ring and SCE (V_{Au}), between the GaP ohmic contact and SCE (V_{GaP}), and between the GaP ohmic contact and the Pt cathode (V_{cell}). V_{Au} , V_{GaP} and V_{cell} were first noted for the open-circuited (o.c.) cell, dark and then illuminated. Measurements of these potentials were then repeated for the short-circuited (s.c.) cell, along with observations of current I and time T . No external potential was applied at any time to the cell. N₂ was bubbled through the electrolyte during the measurements.

For the o.c. dark cell, $V_{Au} \sim V_{GaP} \sim +0.09$ V (SCE); for the o.c. illuminated cell $V_{Au} = -0.03$ V, $V_{GaP} = -1.0$ V (initially). We interpret this illuminated result to mean that the initial energy difference between the electron Fermi level, $E_a^i = V_{GaP}$, and $\phi_p = V_{Au}$, equals 0.97 V. The result also shows that illumination has caused a -0.13 V cathodic shift in the Fermi level of the Au film. The photovoltage generated through separation of electron-hole pairs by the electric field of the surface Schottky barrier causes V_{GaP} to shift to -1.0 V versus SCE.

The s.c. results, more characteristic of normal cell operation, are given in Fig. 2. The outstanding feature of the data is the immediate rise of V_{Au} from $+0.08$ V to $+0.92$ V (SCE) when the Au/GaP anode is illuminated. The OH⁻/H₂O redox potential is at $+0.71$ V (SCE) for the pH 4.6 electrolyte so that oxidation of OH⁻ ions by the photoholes is initially possible. There is a sustained rise of I during the first few minutes of illumination together with the associated parallel shift in the cathodic direction of V_{Au} and V_{GaP} . Current I continues to rise even when V_{Au} becomes cathodic to the OH⁻/H₂O potential, indicating that the major part of I is due to oxidation of some species other than OH⁻. There is an initial difference of 0.99 V for $V_{Au} - V_{GaP}$, equal to the initial o.c. potential difference, and the reduction of this difference with time as V_{Au} falls off more rapidly with time than does V_{GaP} .

Fig. 1 Schematic view of cell for measuring V_{Au} . 1, Light from 150-W quartz-I₂ lamp; 2, quartz cell window; 3, polyethylene cell, 2.5 cm wide; 4, 0.1 M K₂SO₄ at pH 4.6; 5, large Pt black cathode; 6, Luggins capillary and SCE; 7, polyethylene mount for anode; 8, Sealit cement; 9, Au/n-GaP anode; 10, DMM having $R_{in} > 10^{10} \Omega$.

Fig. 2 Time variation of gold-film potential (●), bulk n-GaP potential (▲) and cell current (×) during the first 10 min of s.c.-illuminated operation. Note the gold-film potential is anodic to the OH⁻/H₂O redox potential for the first 2 min of operation so that oxidation of OH⁻ by the photoholes is possible.

Agitation of the electrolyte at $T = 14$ min seems to have ruptured the Au film; V_{Au} immediately fell to $+0.08$ V and the current to 37 μ A. Visual inspection of the Au surface from outside the cell showed several dark patches on the Au/GaP surface. Inspection later of the cleaned GaP surface revealed deep corrosion craters directly below where the dark patches had been noted earlier.

Tests of other gold-covered anodes revealed a pattern of behaviour similar to the above, with the exception that the gold surface films seemed to be intact.

Before the results are discussed, the concept of the quasi-Fermi level will be introduced and defined, followed by a brief examination of key features of the Type B film hypothesis⁴.

Because of the low rate of charge transfer between CB and VB of a semiconductor, non-equilibrium concentrations of electrons, $n_0 + \Delta n$, in the CB, and of minority carrier holes, $p_0 + \Delta p$, in the VB, are generated by illumination absorbed in the surface space charge region. Each distribution has in general a different mean free energy and a corresponding quasi-Fermi level. Unless L is very large, $\Delta n < n_0 = 2 \times 10^{17}$ cm⁻³, so that the electron mean free energy and Fermi level remain virtually unchanged by the illumination. But $\Delta p \gg p_0$, the minority hole concentration in the n-GaP, so that Φ_p can be changed drastically by the illumination. Thus

$$\Phi_p \equiv A + kT/e \{ \ln [(p_0 + \Delta p)/n_1] \} \quad (1)$$

$$\Delta p \sim L \tau_p \quad (2)$$

where n_1 is carrier concentration and A the electron Fermi level in an intrinsic GaP semiconductor. τ_p is the hole lifetime near the n-GaP surface.

The model⁴ for the Type B film assumes the existence of a 2 nm thick semi-insulating oxide film between the Au film and the GaP substrate. Photoholes from the n-GaP can tunnel through the oxide film into the Au film. Positive charge and potential build up in the Au film until the rate at which holes

enter the film equals the rate at which holes oxidise redox species, such as OH^- , in the electrolyte. To maintain the net flow of holes and the current in the s.c. cell, Φ_p will be more anodic than V_{Au} , and V_{Au} more anodic than the redox potential of the oxidised species. If the oxide is thin and easily tunnelled through, indicated by an abrupt rise of V_{Au} when L is turned on, one expects $V_{\text{Au}} \sim \Phi_p$. Also in this case the maximum value of $V_{\text{Au}} - V_{\text{GaP}}$ for the o.c. and s.c. cells should be almost equal, in agreement with the results above.

For the s.c. results it is possible to demonstrate a set of relationships between the cathodic shifts of V_{Au} and V_{GaP} and the sustained rise of I during the first few minutes of cell operation. (1) The cathodic shift of V_{GaP} is equal to the shift of the Pt cathode potential as increasing amounts of H are reduced and absorbed on the Pt surface by the photoelectron current originating in the CB of the n-GaP. (2) For constant L , equation (1) indicates that $V_{\text{Au}} - V_{\text{GaP}}$ should remain constant with time. This is not observed, however, instead V_{Au} shifts more rapidly in the cathodic direction than does V_{GaP} . (3) We attribute this observed difference in rate to electrochemical corrosion of the GaP surface beneath the Au film, according to the following sequence: GaP corrosion \rightarrow increased surface recombination rate for electrons and holes \rightarrow reduction in $\tau_p \rightarrow$ reduction in $\Delta p \rightarrow$ reduction in $\Phi_p \rightarrow V_{\text{Au}} - V_{\text{GaP}}$ decreases with increasing time. (4) The sustained rise in I during the first 3 min may be due to a corrosion-generated local increase of H^+ under the Au film⁵ which in turn increases the corrosion rate and I . The intensity L establishes an upper limit for I so that I peaks and then begins to fall off as corrosion reduces τ_p and Δp .

If the above analysis is valid, then the observation of a reduction in $V_{\text{Au}} - V_{\text{GaP}}$ with time can be used as a tool for determining the existence and rate of electrochemical corrosion under the protective Au film. It could thus serve to evaluate photoelectrochemical solar cells and their rate of corrosion in various electrolytes.

Data of Fig. 2 also provide information about the flat-band potential, ϵ_{fb} , of the Au/GaP anode and the possibility of p.e. The VB edge of the Au/GaP anode is more than 0.21 eV below the $\text{OH}^-/\text{H}_2\text{O}$ redox potential since Φ_p must be above the VB edge; Δp in equation (1) cannot exceed the density of hole states in the VB, ϵ_{fb} is approximately 2.23 eV above the VB edge.

During the first few minutes of s.c. operation, when V_{Au} is anodic to the $\text{OH}^-/\text{H}_2\text{O}$ potential, oxidation of OH^- by holes in the Au film is possible. In the absence of an external potential p.e. is not possible since $V_{\text{Au}} - V_{\text{GaP}} \approx \Phi_p - E_i^n < 1.23$ V, the p.e. threshold, at all times. Equation (1) shows that a 10^4 -fold increase in L and Δp would be required to make $V_{\text{Au}} - V_{\text{GaP}} \approx 1.23$ V. A Pd film evaporated on to the surface of the Au film⁴ will not alter this conclusion (in agreement with some preliminary results).

Finally, we may conclude that in almost neutral aqueous electrolytes a n-GaP surface cannot be protected from electrochemical corrosion through use of a porous gold film evaporated on to its surface.

The first cubane-type fluoro-bridged cluster

CUBANE-TYPE clusters containing the unit M_4A_4 have been the subject of many investigations. Several of these systems have been characterised by X-ray structure determination. Such clusters are important from a bioinorganic point of view, for example, Fe_4S_4 clusters in iron-sulphur proteins¹. From a catalytic point of view, clustered compounds are becoming increasingly important as models for heterogeneous catalysts, and even as catalysts by themselves². Monoatomic ligands (for example, $\text{A} = \text{S}, \text{Cl}, \text{P}, \text{Br}, \text{Se}$) have been reported as bridging ligands in cubane-type clusters, but larger groups are known in which C, N, and O act in a similar way³. No cubane-type clusters have been previously reported with the highly electronegative F^- ion as a bridging ligand. We describe here the synthesis and structure of the first fluoro-bridged cubane-type cluster, having the formula $[\text{M}_4\text{F}_4(\text{L})_{12}] (\text{BF}_4)_4$, in which $\text{M} = \text{Mn}, \text{Cd}, \text{Co}$ and $\text{L} = N\text{-ethylimidazole}$ or $N\text{-propylimidazole}$. On reaction of $\text{M}(\text{H}_2\text{O})_6 (\text{BF}_4)_2$ in ethanol-triethyl orthoformate with an ethanolic solution of the ligand, finely-divided white powders (Mn, Cd) or purple crystals (Co) separate, analysing as $\text{M}(\text{ligand})_4\text{BF}_4$. In these circumstances the F^- ions are spontaneously generated by a slow decomposition of the BF_4^- ion. Such a decomposition of tetrafluoroborates, yielding fluoro complexes, has been reported in a few other cases, yielding polymeric fluoro-bridged systems⁴, dimers $(\text{M}_2\text{F}_2)^5$ and also monomers MF_2 (ligand)₄ (ref. 6).

X-ray powder diagrams showed all compounds to be mutually isomorphous. Infrared spectra indicate the presence of uncoordinated BF_4^- ions. Ligand-field spectra of the Co(II) compounds indicate a six-coordinate octahedrally-based geometry for Co(II) , whereas magnetic measurements at low temperature (2–80 K) show the presence of a weak anti-ferromagnetic exchange ($-J \sim 1 \text{ cm}^{-1}$) between the Co(II) ions. The strong far-infrared absorptions around 300 cm^{-1} suggest the presence of bridging M-F-M units. From these physical measurements a cubane-type structure was proposed. To verify this

Fig. 1 Cubane-type cluster of $\text{Co}_4\text{F}_4 (N\text{-ethyl imidazole})_{12}^{4+}$ with the first coordination sphere around cobalt. Mean distances and angles are: $\text{Co-F} = 2.14(2) \text{ \AA}$; $\text{Co-N} = 2.19(3)$; $\text{Co-Co} = 3.29(2)$; $\text{F-F} = 2.71(1)$; $\angle \text{F-Co-F} = 78.5(5)^\circ$; $\angle \text{Co-F-Co} = 100.5(5)^\circ$.

proposal a crystal-structure determination was undertaken.

An octahedrally shaped crystal of $\text{Co}(\text{N-ethylimidazole})_2\text{BF}_4$ having the approximate edges of 0.2 mm was selected. The crystal belongs to the cubic space group Pa3 with $a = 25.797(1)$ Å. The experimental density of about 1.4 g cm^{-3} indicates that 32 CoL_2BF_4 units are present in the unit cell. One unit occupies an eightfold position (the threefold axis); the other one is in a general 24-fold position. The cluster, consisting of four CoL_2BF_4 units, has trigonal symmetry. At the present stage of refinement $R_F = 0.13$. The cluster is drawn in Fig. 1. The trigonal clusters can be considered as being built up by two interpenetrating tetrahedrons. The F_4 tetrahedron is symmetric: all F-F distances are equal within experimental error. The Co_4 tetrahedron has a larger edge and is slightly elongated in the trigonal direction: $\text{Co-Co} = 3.28\text{--}3.31$ Å. This relatively large Co-Co distance suggests at best a weak Co-Co bonding. The Co-F and Co-N distances have normal values compared to other octahedrally coordinated Co(II) compounds. The BF_4^- ions are located outside the cluster; one BF_4^- is on the trigonal axis, whereas the other anion is in a general position. Due to disorder the orientation of the BF_4^- anions cannot be determined accurately.

The Co-F-Co angles of about 101° are important in understanding the low-temperature magnetic behaviour of this compound. According to De Jongh and Block⁹ bond angles larger than 90° should result in antiferromagnetic behaviour, in agreement with the experiments.

Hydrothermal manganese in the Galapagos Rift

HYDROTHERMAL emanations originating at mid-ocean ridges have been thought¹⁻⁵ to provide a substantial source of manganese to the ocean but the evidence supporting this hypothesis has been indirect. Anomalous manganese concentrations have been measured in naturally occurring systems where seawater is in direct contact with lava flows⁶⁻⁸. Laboratory studies have shown that seawater tends to leach manganese from basalts at elevated temperatures and pressures⁹⁻¹¹. Anomalous high manganese accumulation rates have also been determined for sediments adjacent to active ridge systems, most notably the East Pacific Rise¹²⁻¹⁴. No measurements of manganese concentrations in seawater near mid-ocean ridges, or in hydrothermal fluids emanating from these ridges, have yet been made, however. We report here the results of the first such direct measurements, which show that manganese is being injected into the deep sea by hydrothermal circulation of seawater

through newly-formed oceanic crust.

We analysed water samples collected in the Galapagos Rift during two cruises of the RV Melville (Pleiades expedition, Legs 1 and 2). These samples were collected from hydrocasts and with a remote-controlled sampler attached to the Deep Tow vehicle of the Scripps Marine Physical Laboratory¹⁵. Unfiltered aliquots of these samples were acidified to pH 2 with redistilled 6M HCl. Manganese was determined by addition of radioactive ⁵⁴Mn,

Fig. 1 The concentrations of TDM plotted against depth for samples collected from hydrocasts at two Pacific locations. ●, Samples collected during the Geosecs program at station 343 ($16^\circ 31.6' \text{N}$, $123^\circ 1.4' \text{W}$). △ And ○, samples from eight Pleiades Expedition stations taken at the Galapagos Rift survey site ($0^\circ 35.5'$ to $0^\circ 48.0' \text{N}$, $86^\circ 4.7'$ to $86^\circ 10.2' \text{W}$; see map ref. 15) △, Pleiades Leg 1; ○, Pleiades Leg 2. ▲, Deep Tow samples, although results for samples 7-0 and 8-3 are not plotted. The size of the symbols approximates the analytical uncertainty of the measurements.

adjustment of the pH to 8, extraction of manganese into 8-hydroxyquinoline in chloroform, and back extraction into 3M HNO_3 (ref. 1). Manganese concentration in the 3M HNO_3 solution was measured using an atomic absorption spectrophotometer with a graphite furnace and the yield was determined by counting the 835 keV ⁵⁴Mn γ ray. From these data and the volumes of the initial sample and concentrate, the manganese concentration of the initial sample was calculated. This value, which is believed to include all dissolved and particulate manganese except that fraction in the lattice of silicate minerals, is called 'total dissolvable manganese' (TDM)¹.

Figure 1 shows how TDM concentrations vary with depth at two separate locations. The shaded circles represent samples collected during the Pacific Geosecs program at station 343 ($16^\circ 31.6' \text{N}$, $123^\circ 1.4' \text{W}$). Of the locations at which we have made these measurements, station 343 is the closest geographi-

cally to the Galapagos Rift. Below 1,000 m, the TDM profile at this station is typical, with concentrations ranging from 0.017 to 0.087 μg per kg. Also shown in Fig. 1 are the TDM concentrations found for the samples collected from hydrocasts over the Galapagos Rift. They include samples taken at one station during Leg 1 and seven stations during Leg 2. These samples show TDM concentrations ranging from 0.046 to 0.90 μg per kg, with a maximum at the depth of the ridge crest in the study area. We believe that these anomalously high concentrations are the result of the injection of hydrothermal plumes into this area. Furthermore, the fact that the TDM concentration increases rapidly with increasing depth implies scavenging of hydrothermal manganese from the water column.

In addition to the high manganese concentrations found in the hydrographic profiles, we have made direct measurements of manganese in hydrothermal plume samples collected in the Galapagos Rift by the Deep Tow sampling system. The hydrothermal origin of these plume samples has been unequivocally demonstrated by measurements of excess ^3He and ^{222}Rn (ref. 16) as well as by the hydrographic evidence¹⁸. The TDM results for the Deep Tow samples are listed in Table 1, together with the ^{222}Rn results¹⁶ for the same samples. Sample 8-3, which had a ^{222}Rn anomaly of 80 d.p.m. per 100 kg, had a small positive $\delta^3\text{He}$ anomaly, and sample 7-0, which had a ^{222}Rn anomaly of 191 d.p.m. per 100 kg, had a large $\delta^3\text{He}$ anomaly. These data show that there is a one-to-one correspondence between the presence of very high TDM concentrations, the hydrographic identification of plumes, and the presence of excess quantities of helium and radon. The TDM concentration in plume sample 7-0 is 50 times the concentration in the surrounding bottom water. TDM is thus an exceptionally sensitive tracer of hydrothermal fluids: dilutions of the order of one part in 10^6 parts bottom water should be measurable.

Table 1 Total dissolvable manganese measurements on samples collected with the Deep Tow vehicle on the Galapagos Rift (0°48'N, 85°55'W), Pleiades Expedition Leg I

Tow no.-bottle no.	TDM (μg per kg)	Excess ^{222}Rn ¹⁶ (d.p.m. per 100 kg)
Samples with potential temperature spikes		
7-0	24	191
8-3	2.1	80
Near-bottom samples with no temperature spikes		
7-1	0.41	39
7-2	0.41	49
8-1	0.77	—
8-5	0.48	—
8-7	0.48	—

Sample 7-0 was collected from a hydrothermal plume with a potential temperature anomaly of $+0.20^\circ\text{C}$ relative to the surrounding bottom water¹⁶. Assuming that hydrothermal water in contact with basalt has a temperature of 100°C (ref. 17), and that a negligible fraction of the TDM in sample 7-0 was scavenged before sampling, we calculate that the manganese concentration in the undiluted hydrothermal solution is 12 mg per kg. This value agrees well with predictions based on measurements of dissolved manganese in seawater basalt systems⁸⁻¹¹.

Our measurements provide the first direct evidence that manganese is injected into the deep water column as a result of leaching from newly-formed crust by hydrothermally circulating seawater. Although further measurements are required to establish the areal and temporal variability of this process, our data suggest that hydrothermal sources represent an important part of the manganese cycle in seawater.

We thank R. Collier, J. M. Edmond, J. Corliss, F. N. Spiess, P. F. Lonsdale, H. Craig, J. Dymond, and the participants of Pleiades Expedition Legs 1 and 2 of the RV *Nelville* who made the collection of these data possible. We also thank A. E. Bain-

bridge and the Geosecs Operations Group for collecting the Geosecs samples. This work was supported by the USNSF.

Solar influence on North Atlantic mean sea level pressure

A PRINCIPAL component analysis (PCA) of mean sea level (MSL) pressure data for the North Atlantic-European sector of the Northern Hemisphere has revealed evidence of a solar-terrestrial relationship. The principal components represent independent atmospheric circulation anomaly patterns and the coefficients give the variation in time of the contribution of each anomaly pattern^{1,2}. The data set described here comprises 101 winter MSL pressure anomalies (relative to the 1874 to 1974 winter average) on a 25-point, 20° longitude by 10° latitude grid covering the area 40°W - 40°E , 30°N - 70°N . Winters (December-February) are dated by the year of the January. The suitability of this grid for calibrating proxy data for the European sector is being investigated as a preliminary stage to the derivation of Holocene climatic information³. The data were obtained from the UK Meteorological Office,

Fig. 1 Second principal component of winter MSL pressure anomalies (mbar). Based on data for the period 1874-1974.

and are likely to contain inhomogeneities due to different analysis techniques⁴ and so on. Some errors have become apparent in the course of the analysis and in general are confined to negligible low variance principal components. Missing data were replaced by the 101-yr mean for the grid point. Similar principal components were obtained by repeating the analysis for 30-yr sub-intervals. A slight latitudinal shift in the patterns occurred and there was some change in the relative importance of the principal components. Detailed results of the PCA are to be published elsewhere.

The second principal component (PC2) accounts for 20% of the variance of the original data set. The pattern is dominated, when its coefficient is positive, by a large negative anomaly area to the south of Iceland and west of the UK (Fig. 1). Positive anomalies occur over north-east Scandinavia. A positive contribution of PC2, therefore, represents intensified cyclonic development centred around 50°N 20°W, corresponding to a southward displacement

Fig. 2 Variance spectrum of the coefficients of PC2.

of the Iceland Low and enhanced southerly airflow over the North Sea. The pattern is inverted if its coefficient is negative.

The variance spectrum of the time series of the coefficients of the second principal component is shown in Fig. 2. Spectral peaks occur centred at 11, 5.0, 3.4 and 2.2 yr. The 11 and 2.2-yr peaks touch and surpass respectively the 95% significance level for an *a priori* choice of period, assuming a white noise null continuum³. The 2.2-yr peak may be associated with the quasi-biennial oscillation, but it is close to the Nyquist frequency. The other three peaks I tentatively assign to the 11-yr sunspot cycle and its harmonics; they are jointly significant at the 95% level⁵. A conservative estimate of the area enclosed by these three peaks is that 25% of the time variance of PC2 is associated with these cycles. This represents 5% of the total variance in the original data set.

Further evidence that the 11-yr cycle in the coefficients of PC2 is associated with solar variation is found by comparing the spatial pattern of PC2 with the pattern of 24-h 500-mbar height change following samples of individual solar flares⁶. Schuurmans' map (Fig. 3) shows an area of negative 500-mbar height anomalies (which can be interpreted as an anomalous upper air trough) over the mid North Atlantic and positive anomalies (an anomalous upper air ridge) over western Europe, with enhanced upper air southerlies over the eastern North Atlantic. The area of negative MSL pressure anomalies in PC2 is situated beneath the region of upper air divergence just ahead of the anomalous upper air trough. Such a region is favourable for cyclonic development and intensification⁷. This close correspondence between PC2 and the upper air circulation anomaly patterns associated with

Fig. 3 500 mbar height change (gpdm) in the 24 h following a solar flare (mean of 81 events). (After Schuurmans⁶.)

high solar activity lends added support to the reality of the solar-terrestrial relationship. As solar flare activity is enhanced at sunspot maximum, the longer period solar effect on the atmospheric circulation seen in PC2 arises through the modulation throughout the 11-yr sunspot cycle of the short-term solar flare effects on the circulation. The physical mechanism by which low energy solar particles emitted in flare events can affect the atmospheric circulation has yet to be identified. The pattern of PC2 is very similar to the MSL pressure difference between sunspot maximum and minimum presented by Parker⁸, based on January data since 1750. An 11-yr cycle is also present in the S index, a measure of southerliness over the UK⁹. This variation in southerliness over the eastern Atlantic is a common feature of all the MSL pressure patterns associated with solar variation discussed here.

The coefficients of PC2, passed through a low pass binomial filter designed to reduce the amplitude of wavelengths less than 10 yr by 50% or more⁵, are shown in Fig. 4. The dates of sunspot maxima are arrowed¹⁰. An in-phase relationship is present during the 1880s and throughout the period 1920–60. It breaks down, however, between 1890 and 1920 and possibly during the 1960s. The relationship between North Atlantic sea temperature and sunspot num-

Fig. 4 *a*, Coefficients of PC2, smoothed with a 9 weight low pass binomial filter⁵. *b*, Dates of sunspot maxima¹⁰. *c*, Volcanic dust veil index, 10-yr averages¹⁴ updated to 1969 (H. H. Lamb, personal communication). *d*, Relative sunspot numbers, 10-yr average anomalies relative to 1949–71 mean¹⁰.

bers, discussed by Muir¹¹ and Colebrook^{12,13} is also weakest about the turn of the century. This apparent variability in the strength of the North Atlantic solar-terrestrial relationship requires further investigation before its predictive potential can be realised. There are three possible explanations for the long-term variability. First, sunspot numbers may not be a good indicator of the particular component of the solar output affecting the atmospheric circulation. Second, the volcanic dust loading of the stratosphere was minimal during the period 1920-1960¹⁴ (Fig. 4c) and this may have resulted in a stronger solar control on the atmospheric circulation during that period. At other times, the volcanic control may mask the solar effects. Third, the amplitude of the sunspot cycle was far greater after 1920 than before (Fig. 4d).

The principal component analysis of the MSL pressure data is to be extended to other sectors of the Northern Hemisphere Proxy data for areas where the solar-terrestrial relationship is strongest are to be used to lengthen, the record of this 11-yr climatic variation and to identify the cause of the longer-term variation in its strength.

Copper exclusion as a mechanism of heavy metal tolerance in a green alga

ORGANISMS isolated from environments polluted by heavy metals are often tolerant of those metals¹⁻⁵. Tolerance is usually accompanied by metal uptake equal to or greater than that of non-tolerant organisms^{2,6-10}; the accumulated metals seem to be chemically detoxified and/or physically sequestered to render them inactive^{2,6,7,11-13}. Because heavy metal tolerant algae¹⁰, plants², yeast⁷ and invertebrates^{1,10} have been found not to restrict metal uptake, metal exclusion has been considered a rare mechanism of tolerance⁹. I report here, however, that a copper-tolerant strain of the common unicellular green alga *Chlorella vulgaris* excludes copper.

Two strains of *Chlorella vulgaris* Beijerinck 1890 var. *vulgaris* Fott et Nováková were isolated from the River Hayle, which drains disused copper mines in Cornwall, England. The non-tolerant strain came from a site upstream of mining influence where copper was not detectable in the water ($<0.002 \text{ mg l}^{-1}$). The tolerant strain came from a polluted site with a total copper concentration in the water of $0.12 \pm 0.03 \text{ mg l}^{-1}$ (mean \pm s.e.m. of four samples taken during 1975-76.) To eliminate any non-genetic variation between the isolates, clones of each strain were subcultured approximately 30 times on Bold's basal medium agar¹⁴.

The effect of copper on the growth rates of the tolerant and non-tolerant strains is shown in Fig. 1. Although copper

Fig. 1 The effect of copper added to the medium on the growth rate of tolerant (●) and non-tolerant (○) strains of *Chlorella vulgaris*. Cultures were grown axenically in defined medium with constant light (8,000 lx supplied by 10 40-W warm white fluorescent tubes) and temperature ($24 \pm 1^\circ \text{C}$). The medium contained: 0.20 mM NaNO_3 ; 0.04 mM MgSO_4 ; 0.07 mM CaCl_2 ; 0.25 mM NaCl ; 0.006 mM K_2HPO_4 ; 0.024 mM KH_2PO_4 ; 5.0 mM PIPES (piperazine-*N,N'*-bis [2-ethane sulfonic acid]) at pH 6.2; plus 0.01 ml l^{-1} of each of the standard Bold's basal medium micronutrient solutions¹⁴ but without EDTA. The pH was 6.2 at the beginning and end of growth. Cultures were of 50-ml volumes in 250-ml conical flasks and were aerated by shaking at 60 oscillations min^{-1} on a reciprocal shaker. Copper was added as $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$. Growth was followed as turbidity using an Evans Electroselenium nephelometer with a green filter (OGR1). Growth rates were computed from a least squares fit to the linear phase of the growth curves and are expressed as the reciprocal of the doubling times in h. Each point is the mean of three cultures, bars represent the standard errors of the mean.

Fig. 2 The amount of copper, as percentage dry weight, accumulated by the tolerant (●) and non-tolerant (○) strains of *Chlorella vulgaris* against the amount of copper added to the medium. Stationary phase cells were centrifuged at 500g for 30 min, washed three times with 50-ml volumes of distilled water, and filtered on to washed and pre-weighed Gelman membrane filters (0.45 μm pore diameter). After drying at 70°C for 24 h, filters were weighed to determine dry weight yield, boiled in 10 ml Aristar HNO_3 to near dryness, taken to 5 ml with distilled water, and analysed for copper with an Evans Electroselenium 240 atomic absorption spectrophotometer fitted with a Shandon Southern Instruments A3470 flameless attachment (carbon rod). Results are expressed as percentage dry weight as copper, computed as the amount of copper accumulated by the algae divided by the total dry weight yield of each culture, $\times 100$. At 0 mg l^{-1} copper, the total yields of the two strains were equivalent. With increasing copper, the yields were reduced; for both strains, the minimum yields, at the highest copper concentrations, were 60% of those of the 0 mg l^{-1} copper controls. Each point is the mean of three cultures, except those points at copper concentrations at which not all cultures grew, namely, the non-tolerant strain at 0.25 mg l^{-1} copper (mean of two cultures) and the tolerant strain at 1 mg l^{-1} copper (one culture). Bars represent standard errors of the mean.

reduced the growth rates of both strains, the tolerant strain was much less sensitive. A copper concentration of as little as 0.05 mg l^{-1} decreased the growth rate of the non-tolerant strain, and 0.30 mg l^{-1} was completely inhibitory. The tolerant strain, however, was not affected by 0.10 mg l^{-1} , and one of three cultures at 1.00 mg l^{-1} survived and grew.

Other reported effects of heavy metals on unicellular algae—increased lag period^{15–17}, increased cell size^{15,16,18} and decreased yield of cell number^{4,18} and dry weight¹⁹—were observed with both strains. The appearance of giant cells, up to 20 times the normal volume, reflects an uncoupling of growth from cell division; as pointed out previously^{15,18,20}, this phenomenon indicates that heavy metals may specifically inhibit division in algae. Also, early in the growth phase, dividing cells failed to separate, resulting in multicellular aggregates, which persisted until late log phase. Thus it seems that heavy metals also affect cell separation.

Figure 2 shows that the non-tolerant strain accumulated 5–10 times more metal at comparable external copper concentrations than did the tolerant strain. The growth rate of each culture as a function of the amount of copper accumulated by the algae is shown in Fig. 3. The lack of difference between the two strains implies that they respond identically to the same amount of cellular copper. Other growth parameters, for example, lag period and yield, are

Fig. 3 The relationship between the growth rate of each culture and the amount of copper, as percentage dry weight, accumulated by the tolerant (●) and non-tolerant (○) strains of *Chlorella vulgaris* grown at various external copper concentrations. Growth rate is the reciprocal of the doubling time in h.

also identical in the two strains at equivalent cellular copper concentrations. Thus copper exclusion is likely to be the only mechanism of tolerance in this alga.

There have been a few reports of metal tolerant organisms that exclude metals. Micro-organisms commonly accelerate the vaporisation of mercury^{21,22}, although Davies¹⁸ reported that the mercury tolerance of the marine alga *Dunaliella tertiolecta* was primarily due to internal detoxification. Bryan and Hummerstone⁸ found a zinc-tolerant marine polychaete, *Nereis diversicolor*, to be impermeable to zinc, cadmium and manganese; copper tolerance in this animal may also result in part from decreased permeability²³. Other zinc-tolerant organisms, including the freshwater bryophyte *Scapania undulata*²⁴, and several species of freshwater filamentous algae (my unpublished results), also seem to exclude zinc.

Because algae form the base of many aquatic food chains, a mechanism of tolerance involving the exclusion of metal may be important to the ecology of polluted environments. A metal that is not accumulated by primary producers is less likely to be concentrated in higher trophic levels.

Genetic variation in wild populations of rain-forest trees

In the tropical rain forest, many tree species grow close together, and they are apparently equivalent in their edaphic requirements and spatially interchangeable. Most species occur at low density although they may be geographically widespread. No other plant community contains as many species of a single life form as do certain mixed dipterocarp forests of the aseasonal wet lowlands of Malesia^{1–3}. Such a population structure and level of diversity makes it hard to see how speciation has occurred. Spatial isolation of individuals and the abundant, normally hermaphrodite flowers simultaneously available for fertilisation in the canopy of the dipterocarp emergents suggest the possibility of self-fertilisation, but many of the understorey species are dioecious. As part of a comparative study of the reproductive biology of rain forest tree species, intra-specific genetic variation of isozymes has been demonstrated for the first time in an emergent and an understorey species of rain forest trees. Polymorphism is common in both species and there is evidence for short-range spatial heterogeneity in gene frequency and also in leaf morphology.

The species studied were *Shorea leprosula* Miq. an emergent species, and *Xerospermum intermedium* Radlk. an understorey species. *S. leprosula* is a dipterocarp which occurs widely in Thailand, Sumatra and Malaysia. *X. intermedium* is a member of the Sapindaceae which includes *Nephelium lappaceum*, the rambutan. Except in Malaysia and Borneo, where it is common on well-watered slopes, its distribution and abundance throughout South-East Asia is not yet known. Samples were collected from three sites, mostly from the Pasoh Forest Reserve which is in the southern part of Peninsular Malaysia.

Electrophoretic analysis of aqueous extracts of leaves was performed in starch or acrylamide slab gels and, after separation, gels were treated to identify the presence of esterases, leucine amino-peptidase, glutamic-oxalacetic transaminase, acid and alkaline phosphatase and also an

unidentified enzyme which proved useful in *S. leprosula*. Initial difficulties in resolving enzymes, especially in *X. intermedium*, were overcome by incorporating polyvinyl pyrrolidone, diethyldithiocarbamate and mercaptoethanol in the extraction buffer at pH 8.6; technical details will be reported elsewhere. Control extracts were incorporated in all runs and the R_F values were adjusted to the value in the reference sample to allow comparisons between gels. In most systems there was evidence of age-related changes in gene activity and so comparisons are confined within single age groups, for example, seedlings or mature trees, and refer to the presence or absence of a band at defined R_F positions.

In addition to the electrophoretic evidence the study has included for *X. intermedium* an analysis of variation in leaf morphology between trees in relation to their distance apart. Evidence of a somewhat different kind has been provided by comparisons of electrophoretic patterns in ten species of *Shorea* with morphological differences between them.

In *S. leprosula* in which 80–250 individuals were sampled per enzyme system, there is striking evidence of genetic polymorphism at alternative R_F positions. Table 1 shows that more than half the total number of positions, pooled over all systems, show variation while the frequency of the rarer state is 0.10 or above. This indicates high levels of polymorphism and hence of heterozygosity. We cannot yet determine the number of loci involved. Tests of independence of presence or absence of bands for all possible pairs generally indicate independence but not always so, probably due to determination of more than one band by a single locus. Column B of Table 1 allows for such correlations and the actual number of loci probably corresponds more closely to the bands referred to in column B than to those in A. Thus *S. leprosula* resembles many other outbreeding species in being highly heterozygous.

Table 1 Combined record of variation in *Shorea leprosula* shown by electrophoretic systems

	A Total no.	B Adjusted no.
R_F positions	40	36
% with variable band presence	55	50

In *X. intermedium* fewer systems were studied and the number of bands per system was less than in *S. leprosula*. In samples from 56 trees, six putatively distinct loci were identified and two of these, both determining esterases, were polymorphic. Comparisons from wild individuals as well as test crosses suggested the occurrence of a pair of alleles at each locus, one active and the other null, with a frequency of 0.97 and 0.49 for the active alleles in the 'fast' and 'slow' positions, respectively. Each locus conformed to the Hardy-Weinberg distribution and each apparently segregated independently of the other. Thus the genetic situation in this species seems to be essentially the same as in *S. leprosula*.

Spatial heterogeneity was evident in *S. leprosula*. Samples derived from groups of trees separated by approximately 700 m are likely to differ significantly at one or more R_F positions. There is also evidence that the degree of difference is correlated with distance apart and this may be related to limited dispersal of pollen and fruit. For *X. intermedium* there are similar indications; heterozygotes often occur between or close to alternative heterozygotes. In this species, variation in leaf morphology has been studied in samples of generally ten leaflets from 68 trees growing in an area 600 m². Analysis of variance within

and between trees for leaf length, breadth, vein number, ratio of vein number to length and ratio of leaf length to breadth revealed highly significant heterogeneity between trees. The distance between any pair of trees can be computed from the coordinates of a rectangular grid applied to a map of the trees' location. The regressions of differences for all possible pairs for the leaf characters on distance apart proved highly significant ($P < 0.001$). How far genetic variation contributes to the variation in the leaf characters is not known but this evidence is not inconsistent with that from the electrophoretic study.

The electrophoretic patterns of 10 species of *Shorea* were compared for esterases, glutamic-oxalacetic transaminase and alkaline phosphates. An index of similarity (I) refers to the ratio of bands in common to total bands identified⁴. Combining the systems the total band number ranges from

Table 2 Values of I based on gel-band patterns in comparisons of species of the genus *Shorea* with *S. leprosula*

Species	Total no. of bands	I
<i>S. curtisii</i>	32	0.500
<i>S. parvifolia</i>	33	0.424
<i>S. acuminata</i>	29	0.413
<i>S. dasyphylla</i>	29	0.275
<i>S. macroptera</i>	31	0.258
<i>S. lepidota</i>	27	0.222
<i>S. macrantha</i>	29	0.137
<i>S. hemsleyana</i>	29	0.103
<i>S. ovalis</i>	35	0.000

27 to 35. Table 2 shows the paired comparisons between *S. leprosula* and nine other species. There is good agreement between I value and taxonomic affinity². Thus *S. leprosula*, *S. parvifolia* Dyer and *S. curtisii* Dyer ex King are taxonomically close and agree in having high I values. Indeed for *S. leprosula* and *S. curtisii* we have the highest I value of 0.5 and for these two species hybrids have been identified in the field. Comparison with *S. ovalis* (Korth.)Bl. provides a zero value consistent with its taxonomic position in a separate section of the genus. It is likely that such electrophoretic evidence will make a valuable contribution to the taxonomy of dipterocarps and probably other groups where specific distinctions are often hard to define.

In *S. ovalis*, a tetraploid, 40 seedlings were collected from the base of four possible parent trees and examined by electrophoresis; altogether 36 R_F positions were available for comparison and of these only two, both esterases, were variable. The low level of variation in this species may be related to self-fertilisation (H. T. Chan, work in preparation).

We infer from the evidence reported here that both the emergent species *S. leprosula* and the understorey species *X. intermedium* have an outbreeding system, combined possibly with short-range heterogeneity in gene frequency which may be related to predominantly short-range pollen and fruit dispersal. The latter conditions contribute to physical isolation between populations and hence may promote speciation. Our findings are being compared with evidence relating to cytology, fertility, pollination mechanisms and breeding structure to set the evolutionary problems of rain forest trees in better perspective.

Freezing avoidance by deep supercooling in hydrated lettuce seeds

Dry seeds of several species survive exposure to extremely low temperatures, including immersion in liquid air for up to 60 d (refs 1–3), but most young seedlings are very susceptible. Fully hardened twigs of several northern tree species tolerate freezing in liquid nitrogen (-196°C) (ref. 5), and deep supercooling seems to be an important mechanism for the avoidance of freezing in both xylem ray parenchyma and flower buds of many other hardy but less cold resistant, deciduous, woody species^{6,7}. Resistance to freezing stress in seeds has been suggested to be related to water content^{1,4,8}, but little attention has been paid to either the relationship between stage of germination and degree of freezing resistance or the nature of the resistance. We report here that hydrated lettuce seeds (achenes) can avoid injury by deep supercooling and that the level of resistance can be determined precisely by differential thermal analysis (DTA). Furthermore, we show that the

deep supercooling is dependent on the intact structure of the endosperm.

Experiments were conducted with seed of Grand Rapids lettuce. Moisture content was controlled by leaving seeds to imbibe water for specific intervals; by leaving them to imbibe in different concentrations of polyethylene glycol (molecular weight 6,000, PEG 6000) for specific intervals, and by storing them at controlled relative humidities in closed vials on top of various concentrations of H_2SO_4 . Moist seeds were dried rapidly between filter papers and samples were prepared for freezing and for determination of water content. Seeds that had imbibed in polyethylene glycol were washed three times with distilled water before preparation. Dry weight was determined after drying at 105°C for 24 h. Moisture content was calculated as percentage water of fresh weight. Supercooling nucleation points were determined by DTA (ref. 7) with an automatically controlled, liquid- N_2 -cooled Cryoson freezing system, with a constant freezing rate of 20°C per h. Exotherms were recorded on potentiometric recorders, at 0.5 mV, connected to the samples with 0.5 mm copper-constant thermocouples. Between 1 and 10 seeds were used with each recording channel. Samples (10 to about 100 seeds) for survival tests were removed from the freezer at predetermined temperatures and kept at 2°C for 2–4 h before ability to germinate was tested in light at 24°C . Seeds were counted after 3 d and the percentage of germinated and growing seeds was used as a criterion for viability.

Lettuce seeds with 5–13% water content were not injured by freezing to -196°C , but with 13–16% moisture, the threshold of freezing tolerance declined to -40°C (Fig. 1a). No exotherms were detected by DTA in either case but two types of exotherms were found in intact seeds

Fig. 1 Relationship between seed water content and hardness in Grand Rapids lettuce seeds. *a*, Limited for 100% survival of seeds stored at 18°C or at 4°C in controlled humidities for 10–14 d. Hardiness at -196°C was tested by keeping the seeds in liquid nitrogen for 30 min. *b*, The mean temperature of the secondary exotherms in seeds imbibed at 30°C in various concentrations of PEG 6000 (0.06–0.12 molal). Open symbols: 5 min red (R) light, $4.2 \mu\text{W cm}^{-2}$ at 660 nm, given after 2 h imbibition in darkness; closed symbols: darkness. \square , \blacksquare , 12 h imbibition; \circ , \bullet , 24 h; ∇ , 72 h; \blacktriangle , 96 h. Regression equation: $y = -0.43x + 33.9$, $r = -0.84$, $P < 0.001$. *c*, Mean temperature of secondary exotherms in seeds imbibed at 30°C in water for 4–72 h. \circ , R; \blacktriangle , R plus 5 min far-red (FR), $24 \mu\text{W cm}^{-2}$ at 730 nm; \blacktriangle , darkness; \times , germinated seeds.

containing more than 20–25% water (Fig. 2). The first appeared as a single peak when the temperature of the sample was $-10 \pm 2^\circ\text{C}$ regardless of the number of seeds in the sample, indicating that the nucleation point for this peak is remarkably uniform. This exotherm is not related to the injury of intact seed and we suggest that it represents freezing of extracellular or bulk water in the outer layers, similar to extracellular freezing of other plant tissue⁷. Each seed frozen showed one deep supercooling exotherm. These secondary exotherms represent the killing point of individual seeds. In seeds imbibed in PEG 6000 the mean exotherm temperature was linearly correlated ($r = -0.84$, $P < 0.001$) with the moisture content within the limits of 20–40% (Fig. 1*b*). A plateau was reached at 40–50% moisture where the mean exotherm temperature of intact seeds remained at $-16 \pm 2^\circ\text{C}$ ($r = 0.004$), irrespective of imbibition time (4–72 h). There was no effect of red (5 min, $4.2 \mu\text{W}$

Fig. 2 Differential thermal analysis of lettuce seeds with moisture contents at various levels. Ten seeds in each sample. Figures and arrows show the percentage of survival (germination) in samples removed at temperatures indicated, those in parentheses show survival of samples frozen down to -35°C . Freezing rate 20°C per h in all cases. To obtain the various moisture levels seeds were imbibed at 30°C in darkness either in water for various times (*a–i*) or in various molal concentrations of PEG 6000 (*j–m*) for 24 h. *a*, 0 or 5 min imbibition, 5.7–16% water content; *b*, 10 min, 20%; *c*, 20 min, 26%; *d*, 30 min, 32%; *e*, 60 min, 41%; *f*, 4 h, 49.7%; *g*, 8 h, 49.5%; *h*, 12 h, 48.8%; *i*, 24 h, 51.2%; *j*, 0.12 molal, 21.9% water; *k*, 0.10 molal, 26.0%; *l*, 0.08 molal, 33.3%; *m*, 0.06 molal, 38.2%.

Fig. 3 Differential thermal analysis of lettuce seeds. *a*, Intact seeds; *b*, seed coats removed; *c*, excised embryos; *d*, endosperms; *e*, intact seeds stuck four times with a needle; *f*, germinated seeds. Figures and arrows are as in Fig. 2. Seeds coats and endosperm were removed with a scalpel under a stereoscope in light after an imbibition at 30°C for 16 h. Seeds stuck with a needle were imbibed in water for 4 h at 30°C . There were ten seeds or embryos in each sample.

$\text{cm}^{-2} \text{nm}^{-1}$ at 660 nm) or far red (5 min $24 \mu\text{W cm}^{-2} \text{nm}^{-1}$ at 730 nm) irradiation on the position of the secondary exotherms up to 8 h after exposure of seeds.

The freezing pattern changed considerably, however, after disruption of the endosperm–seed coat envelope. As soon as the radicle emerged the secondary exotherms disappeared and the first exotherm represented the killing point of the seed (Fig. 3). Similarly, embryos excised from the seeds after imbibition for 2–12 h produced only one exotherm and did not survive below this nucleation temperature (Fig. 3). The occurrence of secondary exotherms depends on the intact structure of the endosperm. If fruit coats were excised carefully without injury to the endosperm envelope, embryos did supercool as detected by the presence of secondary peaks at the nucleation points, but if the endosperm was damaged, for example with a needle, deep supercooling ceased and death was coincident with the first peak (Fig. 3).

Therefore the integrity of the endosperm envelope seems to facilitate deep supercooling which concurrently imparts freezing avoidance to -12° to -18°C in intact, imbibed lettuce seeds. Deep supercooling of lettuce seeds is not, however, an exclusive property of live seeds: it also occurred with intact, imbibed seeds which had been killed by low or high temperatures. Work with apple stems has shown that intact dead twigs yield exotherms if rehydrated to 20% water but not if ground to a fine powder⁸.

The mechanism by which the intact endosperm imparts freezing avoidance to the embryo is not clear. Perhaps disruption of the endosperm facilitates intimate contact of relatively pure water in the coats with the water in the embryo, thus providing ice crystal formation in all parts of the seed at the first exotherm. Germinated

seeds contain slightly more water than imbibed non-germinated seeds, and perhaps endosperm injury increases embryo water content. But even embryos excised from seeds imbibed in 0.10 molal PEG 6000 and kept in 0.12 molal PEG 6000 during freezing did not yield secondary exotherms.

The mechanism of freezing resistance in lettuce seeds seems to resemble those found in other tissues and species at various stages of cold hardiness. We suggest that lettuce seed offers a useful system for the study of mechanisms of freezing tolerance and avoidance.

Guard cell malic acid metabolism during stomatal movements

THE mechanism by which stomata open and close has long been a puzzle, but only now are we beginning to make major advances in our understanding of their metabolism. It has been concluded that guard cells can fix CO_2 and incorporate it into starch¹⁻³. It has been shown that the bulk of, if not all, the CO_2 fixed by guard cells is converted to oxaloacetic acid (OAA) by phosphoenolpyruvate carboxylase and the OAA, in turn, is reduced to malic acid^{3,4}. Some amination of OAA producing aspartate has also been detected⁴. Although there is indirect evidence suggesting that aspartate and/or malate can provide carbon for starch synthesis in the guard cells⁴ direct evidence for this is lacking. We have investigated some characteristics of guard cell CO_2 fixation which directly results in organic acid formation and we also have direct evidence that malic acid is a precursor of starch formation.

Microautoradiography showed that guard cells in epidermal strips of *Commelina communis* L. were able to fix CO_2 in the light or the dark irrespective of whether stomata were open or closed. Although some localisation of ^{14}C could be detected in the region of the epidermal cells the label was concentrated within the stomatal complexes. These observations were confirmed by CO_2 fixation kinetics experiments. Figure 1 shows similar rates of ^{14}C uptake by epidermal tissue of *C. communis* when floated on a $\text{NaH}^{14}\text{CO}_3$ solution in the light or the dark. Slightly greater uptake rates of ^{14}C were obtained in the light when epidermal tissue of *C. diffusa* was cut into small pieces and immersed in $\text{NaH}^{14}\text{CO}_3$ solution⁵.

Microautoradiography also showed that guard cells became more heavily labelled if the epidermis remained attached to the mesophyll. Whether this was due to some channelling of ^{14}C -labelled products from the mesophyll to the guard cells or whether the mesophyll in some way enhances guard cell CO_2 fixation is not known.

When L-(U- ^{14}C)malic acid was fed to epidermal strips of *C. communis* while stomata closed from an aperture of $8\ \mu\text{m}$ in response to darkness, or while they opened from fully closed in response to CO_2 -free air and light, guard cell

Fig. 1 CO_2 fixation kinetics of abaxial epidermal strips of *C. communis* in light (○) and darkness (●). Epidermal strips were floated, cuticle uppermost, on 3 ml 'suspension medium' containing 0.33 M sorbitol, 0.05 M tricine buffer (pH 8.0), 0.002 M sodium nitrate, 0.002 M EDTA, and 0.005 M potassium hydrogen phosphate. At zero time 0.2 ml of 0.05 M $\text{NaH}^{14}\text{CO}_3$ was injected into the suspension medium and the solution quickly swirled to mix, giving a CO_2 concentration of 4.5×10^{-5} M. At the indicated times tissue was immersed in 2.0 ml 20% trichloroacetic acid to stop the reaction and drive off excess $^{14}\text{CO}_2$. Radioactivity in the tissue was then determined by liquid scintillation counting.

starch became labelled in both cases (Fig. 2). Incorporation of label into starch, however, was greatest when the stomata were closing. Microautoradiographs also verified that label from malic acid was incorporated into starch, mainly located in areas corresponding to stomatal positions in the epidermis (blackened areas in Fig. 3). Thus, incorporation of ^{14}C from labelled malic acid into starch is not restricted to closing movements in epidermal strips. But, good correlations for guard cell malic acid accumulation⁶

Fig. 2 Incorporation of ^{14}C from L-(U- ^{14}C)malic acid into starch during 2-h exposure. The abaxial epidermis of *C. communis* was floated, cuticle uppermost, on 20 ml of 10 mM sodium citrate buffer containing 10 mM sodium chloride and 0.086 mg (25 μCi) U- ^{14}C -malic acid, pH 5.5. In one treatment the epidermal strips possessed closed stomata which were stimulated to open to $7\ \mu\text{m}$ after 2 h incubation in light and CO_2 -free air (○) and in the other, stomata were initially open to about $8\ \mu\text{m}$ and were made to close to about $4\ \mu\text{m}$ after 2 h incubation in darkness and normal air (●). At the times indicated, samples of tissue had their ethanol and water soluble products extracted leaving the insoluble starch and the radioactivity in the starch was determined by liquid scintillation counting.

Fig. 3 Microautoradiograph of an epidermal strip of *C. communis* exposed to darkness and normal air for 2 h to close the stomata and after treatment as described in the legend to Fig. 2. Blackened areas located predominantly over the stomatal complexes indicate ¹⁴C label in starch. (Stomata 1, 2 and 3 correspond to the numbered, blackened areas.) The dried epidermis was placed on a glass slide and a piece of Ilford Pan F film firmly taped on top with the emulsion in contact with the tissue. On top of the film was placed another slide and the whole was clamped together with screw-clips. After exposure for 29 d the piece of film was detached from the tape and tissue and developed in Kodak DX-80 developer.

and starch disappearance⁶ have been observed with stomatal opening. We have also found high levels of starch in guard cells of *C. communis* when stomata were closed; this level decreased as stomata opened although starch could still be detected at wide stomatal apertures. This suggests that there is a dynamic flux of carbon between malic acid and starch with the direction of starch production outpacing its breakdown when stomata are closing. Results of an investigation of pathways for malic acid-starch interconversions will be published elsewhere.

In conclusion we have established that malic acid is a precursor of starch synthesis in guard cells of *C. communis*. But, the mechanism of the control of guard cell CO₂ fixation and hence malic acid synthesis, and the control of the production of starch from malic acid in relation to stomatal movements, remain obscure.

Orientation columns in macaque monkey visual cortex demonstrated by the 2-deoxyglucose autoradiographic technique

In the past fifteen years physiological studies of the primary visual cortex in higher mammals have provided evidence for two independent systems of functional subdivisions, ocular dominance columns and orientation columns¹. These two systems are closely related to two important functions of visual cortex: combining at a single-cell level the information that originates in the two eyes, and rearranging the spatial information from the lateral geniculate body so that cells after the initial stage of visual processing come to respond to specifically oriented lines in the visual field.

The ocular dominance columns have been demonstrated anatomically by three different staining techniques^{2–4}. We describe here the use of a new method⁵ which makes possible the anatomical demonstration of the orientation columns.

The original evidence that cells are aggregated according to their response characteristics came from microelectrode recordings¹. In a penetration perpendicular to the cortical surface all cells are dominated by the same eye and all give optimal responses to the same stimulus orientation, whereas in an oblique or tangential penetration there is an alternation of the dominant eye, from left to right and back, and, at the same time, a series of regular changes in optimal stimulus orientation in steps of 10° or less, clockwise or counterclockwise. Reversals in direction of rotation occur sporadically, on the average every few mm, and the orderly sequences of small orientation shifts are occasionally broken by abrupt large shifts of up to 90°. A full cycle of either type, one eye and then the other or a rotation through 180°, generally requires a horizontal movement along the cortex of 1 mm or less². The constancy of eye dominance and of optimal stimulus orientation during perpendicular penetrations indicates that the two sets of subdivisions are arranged perpendicular to the surface and the layers. Because of their cross-sectional shape in brain sections perpendicular to the surface, the subdivisions have been called 'columns', and a complete set of columns (left plus right eyes, or a full 180° rotation) is called a hypercolumn.

Inspection of cortical sections stained by conventional methods gives no hint of these vertical subdivisions. The only obvious segregation of cells is the horizontal system of layers, and this segregation has certain physiological correlates. Layer IVc, at about mid-cortical thickness, is the site of termination of the geniculate afferents and contains cells that differ in their physiological properties from cells in the other layers in two respects: like the geniculate afferents, they have no orientation preference; and they are almost all strictly monocular. In contrast, cells in the layers above and below IVc almost all show clear orientation specificity and about half are binocular, though any given cell is likely to respond best to one or the other eye.

In the last few years considerable progress has been made in working out the geometry of the columnar subdivisions. Three independent anatomical methods have made it possible to see the ocular dominance columns in layer IVc^{3–6} where they form a set of parallel bands which are for the most part straight, but in places form loops and whorls and occasionally show bifurcations and blind endings. The columns must therefore have the form of parallel sheets rather than being pillar-like. For the orientation columns,

¹ Shaw, M. & MacLachlan, G. A. *Can. J. Bot.* 32, 784–794 (1954).

² Nishida, K. *Physiologia Pl.* 16, 281–298 (1963).

³ Willmer, C. M., Pallas, J. E., Jr & Black, C. C., Jr. *Pl. Physiol.* 52, 448–452 (1973).

microelectrode recordings, especially multiple parallel penetrations, likewise suggest an arrangement in parallel sheets, and the frequent reversals in direction of rotation would be compatible with a swirling pattern.

Until very recently no method has been available for demonstrating the orientation columns anatomically. Several years ago Sokoloff and his group⁷ developed a procedure for labelling active brain tissue. The method depends on the fact that brain cells, which use mainly glucose as a source of energy, take up 2-deoxyglucose as though it were glucose and metabolise it as far as 2-deoxyglucose-6-phosphate, but no further. This compound cannot easily pass out of the cell, and tends to accumulate. Physiologically active regions of brain may then be identified by the use of radioactively labelled deoxyglucose and autoradiography. This method was used by Sokoloff's group in monkeys in which one eye was stimulated during a 45-min period immediately following intravenous injection of deoxyglucose⁸. (The other eye was occluded in some monkeys and had been previously removed in others.) The result, a striking demonstration of the ocular dominance columns in the striate cortex, differed from the results obtained by the other anatomical techniques in demonstrating the columns through the full cortical thickness, rather than showing just the parts in layer IVc.

We have used the deoxyglucose method to reveal the orientation columns. Our procedure is based on that of Sokoloff and his group, to whom we are indebted for first-hand instruction in the method. We injected a lightly anaesthetised juvenile macaque monkey with ^{14}C -2-deoxyglucose, $150 \mu\text{Ci kg}^{-1}$ in $100 \mu\text{Ci ml}^{-1}$ saline, and then stimulated for 45 min by moving back and forth in front of the animal a black screen on which were pasted a set of irregularly spaced vertical white stripes. Stripe widths were $0.5\text{--}1^\circ$, and movement was $2\text{--}4^\circ \text{ s}^{-1}$. Both eyes were held open, protected by contact lenses, refracted at the screen distance (1 m) and aligned with a variable prism over one eye so that the foveas were superimposed. To be sure of the alignment and as a check on the state of the animal we also recorded from single binocular cells in striate cortex and superimposed the receptive fields.

At the end of the stimulus period the animal was given an additional dose of anaesthesia followed by a lethal dose of intravenous KCl. It was then decapitated, and the skull was cleaned of skin, gradually immersed over a 4-min period in liquid Freon-22 at -125°C , and stored at -80°C . Small blocks of brain were later sectioned at $20 \mu\text{m}$ in a cryostat at -26°C , and the sections were picked up on a cover slip and immediately dried at 98°C . These sections were then pressed against X-ray film for 2–3 weeks and the film was finally developed. Some of the sections used for autoradiography were also later stained for Nissl substance.

An autoradiograph made from a section perpendicular to the striate cortex is shown in Fig. 1. Vertical regions of dense label can be seen extending through the full thickness of cortex. About midway through the thickness is a dense uniformly labelled horizontal band. By comparing the autoradiographs with neighbouring sections stained for Nissl substance it can be shown that this band corresponds to layer IVc. This agrees with the observation from microelectrode recordings, that cells in layer IVc show no orientation specificity. No such uniform labelling was seen in IVc in the results of Sokoloff's group⁸ or in our experiments, when ocular dominance columns were labelled by this method.

The vertical labelled regions in Fig. 1 are on the average about 0.6 mm apart and occupy a considerable fraction of the repeat distance, as expected from the fact that each cell responds not just to a single orientation but to a range of orientations to either side of the optimum, with some cells highly selective and others less so. For example, in a sharply tuned cell the orientation that evokes a half-

Fig. 1 Autoradiograph of a ^{14}C -2-deoxyglucose section through monkey striate cortex, perpendicular to the surface. The stimulus consisted of moving vertical, irregularly spaced white stripes presented to the entire visual field of both eyes for 45 min. Labelled regions are vertical in cross section, about 0.6 mm apart, and extend through the full cortical thickness. Layer IVc, situated at about mid-depth and identified from neighbouring Nissl-stained sections, is uniformly labelled, as expected from the absence of orientation specific cells in that layer.

maximal response may be $10\text{--}15^\circ$ from the optimal. The widths of the labelled regions must depend on many factors including the sharpness of tuning curves (response plotted against stimulus orientation), and the relationship between cell activity and deoxyglucose uptake, and between uptake and the grain density of the autoradiographs.

A tangential section through the dorsolateral surface of the occipital lobe is shown in Fig. 2. The white matter is grazed in two places which appear as pale ovals. These are surrounded by layers VI and V, cut almost tangentially, and here the labelled regions can be seen face-on, forming a complex pattern of rings, loops, and branching stripes. Their separation is strikingly constant, averaging roughly $570 \mu\text{m}$. Only in a few places is there a suggestion of parallel stripes. Surrounding this area is layer IVc, which is again uniformly labelled, and just outside IVc is IVb, where the aggregations of label are particularly dense. Layers II and III are more lightly labelled but also show distinct aggregations. (The dense bands at the extreme left, perpendicular to the surface, are microtome knife artefacts.)

Fig. 2 Autoradiograph of a tangential section through the dorsolateral surface of the occipital lobe (striate cortex) of the same monkey. Dark areas are radioactively labelled. The section grazes white matter (W) in two places, which are seen as pale ovals. Surrounding these are densely labelled sets of orientation columns in layer VI. Outside this is layer V, lightly labelled, and then IV c, which is uniformly labelled with no hint of columnar subdivisions. The upper layers again show densities related to columns. (Dense bands perpendicular to the surface at the extreme left are artefacts produced by the microtome knife.)

More superficial sections from this block, tangent to the upper layers (II–III) rather than to white matter, show an almost identical pattern, as expected from the fact that the labelled regions are perpendicular to the surface.

So far we have examined too few brains to be sure that the pattern of the orientation columns is always as complex in form as that shown here. Ocular dominance columns were examined in the same region as that shown in Fig. 2, by transneuronal autoradiography following an injection of ^3H -proline into one eye two weeks before the deoxyglucose experiment. These showed a more regular pattern of stripes, with a spacing only slightly coarser than that of the orientation hypercolumns ($770\text{ }\mu\text{m}$ compared with $570\text{ }\mu\text{m}$). There was no obvious tendency for the two sets of columns to be related in any simple way: they were not consistently orthogonal, and were certainly not parallel. This result will be published separately⁹.

The anatomical demonstration of the orientation columns provides still another verification of the columnar organisation of the striate cortex. It is reassuring to find such agreement between morphology and physiology, and unusual to find the physiology actually leading the way to a structural description.

Instability of the eye in the dark and proprioception

THE extraocular muscles of most mammals contain stretch receptors which are not necessarily in the form of muscle spindles. The cat, for example, has no muscle spindles, but the oculomotor muscles contain structures, with spiral endings, that are in parallel with the muscle fibres and respond to stretch¹. Most proprioceptive fibres run extraorbitally in the ophthalmic branch of the Vth nerve^{2,3}. The cell bodies of these fibres seem to be located in the mesencephalic root of the Vth nerve⁴. There is electrophysiological evidence of proprioceptive projections to the cerebellum^{5,6}, superior colliculus^{7,8} and visual cortex⁹. The function of ocular proprioception is uncertain, although there is evidence that in man it may be an indicator of eye position in the dark¹⁰. In the cat it seems to have a role in maintaining the binocularity of single neurones in the visual cortex^{11,12}. Because most proprioceptive fibres run into the ophthalmic branch of the Vth nerve, we have investigated eye movements in the alert animal before and after section of this branch. We report here that, in the absence of visual and vestibular stimuli, the eye ipsilateral to the section becomes unstable and performs slow pendular oscillations. Asymmetries are observed in the horizontal vestibular nystagmus recorded in total darkness from the two eyes after unilateral section.

Cats chosen for their docility were anaesthetised with pentobarbital. A plastic cylinder was fixed to the skull and Ag–AgCl electrodes were implanted for recording horizontal movements of both eyes. The cat was trained to stay

Fig. 1 *a*, Electro-oculographic a.c. recordings of horizontal movements of the right eye (RE) and left eye (LE) of a normal cat in the dark. *b*, The same, recorded 1 d after section of the ophthalmic branch of the right Vth nerve and *c*, 1 week after section of the ophthalmic branch of the left Vth nerve. Upward trace deflections indicate rotation of the eyes to the right, downward deflections, rotations to the left. The vertical bar corresponds to 5° horizontal eye rotation. Band pass: 0.1–20 Hz.

in a comfortable box with its head fixed by the plastic cylinder to a holder. The holder could either prevent any head motion or allow head rotations about a vertical axis. The cats were trained, over several days, to perform horizontal eye movements, tracking a visual target with the head either fixed or free to rotate horizontally. Eye movements were calibrated in each session by setting two pointers 30 cm from the eyes and displacing them 15° on either side of the cat's medial plane. The cat's attention was then called to either pointer while an experimenter checked the correctness of fixation, and the corresponding position of the recording trace was marked.

The cat box and the head holder were fixed to a table that could be oscillated sinusoidally about a vertical axis at various amplitudes and velocities.

When sufficient eye movements were recorded, the animal was again anaesthetised and the ophthalmic branch of the right Vth nerve was cut at the exit from the orbit or at the entrance into the semilunar ganglion. A small aperture was made into the parieto-temporal bone and the brain was lifted gently to reveal the three branches of the Vth nerve. Care was taken not to touch the oculomotor nerves. The operation was repeated on the left side after 2 or 3 weeks. After the experiments the animal was killed and the completeness of the section was checked.

We present here only results concerning eye movements in the dark, either spontaneous or elicited by head or body oscillations. The records of horizontal eye movements of normal cats that are awake in darkness contain periods with frequent spontaneous saccades, and periods with very few saccades, but with slow drifts mainly conjugate in the two eyes.

After section of the ophthalmic branch of the Vth nerve

no gross changes in the patterns of visually triggered eye movements were observed.

Seven out of nine cats displayed pendular movements of the eye ipsilateral to the section of the ophthalmic branch of the Vth nerve in the absence of visual stimuli (Fig. 1). The upper traces were recorded before the operation, the middle traces after section of the ophthalmic branch of the right Vth nerve and the bottom traces after further section of the ophthalmic branch of the left Vth nerve. The oscillations may have different amplitudes and frequencies in different cats, as comparison of Figs 1 and 2 (from two different cats) suggests. The frequency of the oscillations, however, was stable for each cat. The highest and lowest frequencies observed were 0.6 and 0.08 oscillations per s, the latter having a larger amplitude. There was no correlation between the occurrence of the oscillations and electroencephalogram activity, but the oscillations were more frequent when the cat was not performing frequent voluntary saccades. The two cats in which regular pendular movements were not observed were particularly restless even when deprived of visual and acoustic stimuli, and the rate of saccades was especially high in their eye movement recordings in the dark.

There were eye oscillations in most cats for at least 1 or 2 weeks after the operation. In three cats eye oscillations were observed a month after the second operation.

The patterns of eye movements induced by sinusoidal oscillations of the head or of the entire body became asymmetric in the two eyes after unilateral section of the ophthalmic branch of the Vth nerve. Alterations were induced in the eye ipsilateral to the section and consisted mainly of a decreased amplitude of the fast components of the vestibular nystagmus recorded in the dark. The patterns of vestibular nystagmus after unilateral section were equal in the two eyes when records were made in the light and were similar to those recorded before section. Details of these results will be reported elsewhere.

As controls, two cats underwent a complete unilateral operation except for the section of the nerves. Neither pendular motions in the dark nor asymmetries in the vestibular nystagmus of the two eyes were observed in these cats.

Fig. 2 *a*, Electro-oculographic d.c. recordings of horizontal movements of the right eye (RE) and left eye (LE) of a normal cat in the dark. *b*, The same, recorded 2 d after section of the ophthalmic branch of the right Vth nerve and *c*, 4 d after section of the ophthalmic branch of the left Vth nerve. Upward trace deflections indicate rotations of the eyes to the right.

The most obvious interpretation of the eye oscillations seen after section of the ophthalmic branch of the Vth nerve is that they result from the opening of the loop of the servo-system device responsible for the maintenance of eye position. Position errors can be signalled by two mechanisms: vision, indicating retinal error, and proprioception indicating relative stretch of the oculomotor muscles. It is not surprising that the interruption of the second source of information brings about oscillations of the eye in the dark.

Leukocytes are consistently associated with degenerating embryos in IUD-bearing rhesus monkeys

IN spite of intensive research during the past 15 yr the precise mechanism whereby an intrauterine device (IUD) exerts its contraceptive action is unclear. There is wide agreement that the effect is intra- rather than extrauterine, and is probably elicited after arrival of the conceptus in the uterine cavity and before its attachment to the endometrium¹. The most plausible suggestion seems to be that the device acts as a foreign body and provides a sterile inflammatory reaction in the endometrium which in some unknown way renders the uterine cavity hostile to preimplantation embryos^{1,2}. The presence of large numbers of inflammatory cells, consisting mainly of neutrophils and, to a lesser extent, macrophages, is a constant feature of the endometrial reaction in IUD-bearing women and other mammals. In some species there is a high positive correlation, in the presence of an IUD, between the concentration of leukocytes in the uterine fluid and the suppression of implantation (for example, in the rabbit³). So far, however, there has been no direct proof of a consistent association between leukocytes and unimplanted embryos in IUD-fitted primates. This paper provides evidence for such an association in the rhesus monkey.

Our study stems from the successful development of a method for the recovery of uterine embryos from normal monkeys⁴. It consists of flushing fluid through a large-bore, fenestrated needle inserted into the uterine lumen above the cervix and aspirating it through a second, fundal needle into a receiving syringe; it has a yield rate of about 50% of preimplantation embryos in animals examined between days 15 and 20 of the menstrual cycle.

Normal females without IUDs were first subjected to the flushing procedure for the recovery of uterine embryos and then fitted with a shortened tailless Margulies coil inserted surgically through the fundus. After two successive menstrual periods the animals were mated and flushed once, as before, between days 15 and 20 of the cycle. The contents of the flush was deposited immediately into a siliconised watch glass and searched under a stereomicroscope. Embryos were transferred to cold 2.5% glutaraldehyde in 0.1 M cacodylate buffer, photographed and processed for

Fig. 1 Blastocyst from IUD-monkey (no. 476), showing leukocytes on the surface and apparently penetrating the zona pellucida ($\times 256$).

electron microscopical examination³. The remainder of the flush was centrifuged and the cellular composition of the pellet was determined by means of a haemocytometer and cytocentrifuge. During initial recovery attempts in IUD-animals, the flush was found to contain far more cells and debris than observed in non-IUD flushes (Table 1) and tended to clot, making the search for embryos difficult; heparin added to the receiving syringe reduced this tendency.

Sixteen females, from all of which embryos had been recovered in the non-IUD condition, have been flushed after being fitted with a device yielding six embryos in a total of 46 attempts (Table 1). Five of these embryos, the sixth being lost in processing, have been prepared and representative sections were examined by light microscopy and with an electron microscope. All five were considered to be abnormal or degenerating and each showed polymorphonuclear leukocytes both outside and within the embryonic tissue (Figs 1–3). In two of them macrophages were also present. In another, judged to be an azonal morula, all blastomeres were fragmenting, with leukocytes infiltrated between them. Two azonal embryos were blastocysts with

leukocytes present in the blastocoel cavities (Fig. 2). Another blastocyst possessed the zona pellucida and, again, leukocytes were found within the blastocoel and interspersed among cells of the inner cell mass. In two cases leukocytes were seen apparently passing through the zona pellucida (Fig. 3). The trophoblast layer showed irregular cells with disorganised cell junctions and an array of cytoplasmic membranous material not observed in normal monkey blastocysts³. The fifth embryo comprised only five or six shrunken cells within an intact zona. Electron microscopy revealed several polymorphs and macrophages in direct contact with embryonic cells. The polymorphs appeared to be typical, mature neutrophils and the macrophages had extensive plasma membrane invaginations. Occasional eosinophils were also present.

By contrast, of a total of three unfertilised ova and 30 embryos so far recovered from non-IUD monkeys, none had any polymorphs or other types of leukocyte attached to the surface, and only eight embryos were considered to be degenerating.

Cytological analysis of all IUD-flushes (irrespective of embryo recovery) showed that the number of cells varied from 4.37×10^5 to 2.39×10^6 , most of them being neutrophils (Table 1). Flushes from non-IUD fitted uteri gave

values between 1.44×10^4 and 3.92×10^5 (mean: $2.32 \pm 0.62 \times 10^5$), most being epithelial cells. By contrast, Joshi *et al.*⁹ reported no significant increase in polymorphs in the uterine flushings of IUD-fitted baboons. Their method of collecting and evaluating the flushes differed, however, substantially from our own. In particular, their use of centrifuge speeds of 2,500g is likely to cause leukocyte destruction, which can be avoided with speeds of less than 750g as employed by ourselves.

Fig. 3 Electron micrograph of the zona pellucida (Z) of an embryo from an IUD-monkey (no. 476). A leukocyte is seen passing through the zona into the blastocoel (B) ($\times 5,550$).

Our findings show that, in IUD-bearing rhesus monkeys, embryos can enter the uterine cavity at about the expected time after conception. They are, however, invariably abnormal or degenerating as well as invested with luminal leukocytes induced by the device. Also, compared with the yield in normal females (about 50%), far fewer embryos can be recovered at corresponding cycle days from IUD-fitted animals (about 13%).

It is feasible that the greatly increased cell content of the flush in IUD-monkeys may have made the detection of a recovered embryo impossible or that the embryo, when flushed out, was already too degenerated to be recognisable. It is also possible that in spite of normal fertilisation and early cleavage, embryos of IUD-fitted monkeys remain 'blocked' at or near the tubouterine junction and are therefore not recoverable by uterine flushing. The conclusion, implicit in our findings, that in monkeys with IUDs the blastocyst stage may be reached is indirectly supported by the finding of increased serum levels of human chorionic gonadotrophin in a proportion of IUD-bearing women examined during the second part of the menstrual cycle^{7,8}. Unfortunately no comparable data are available for rhesus monkeys.

Whether the embryos observed in our study were entirely normal before their investment and penetration by leukocytes is not known. It is possible that the highly cellular milieu of the uterine environment, perhaps derived from dead or dying leukocytes, is embryotoxic and that the main function of recently infiltrating live leukocytes is in the final destruction and removal of dying or damaged embryos. Nonetheless, the demonstrated association between degenerating uterine embryos and their investment with leukocytes in IUD-fitted monkeys is sufficiently constant and striking to suggest that it is more than coincidental.

Active thymus derived suppressor lymphocytes in human cord blood

A FOETUS carries antigens that are foreign to its mother, but the mother does not routinely reject it as an allograft. The fate of the foetus may thus depend on preventing or blocking the ability of the immune system of the mother to respond to alien foetal antigens. Clearly, this is a complex process which may involve several mechanisms¹⁻⁶. One mechanism implicates the active blocking of the immunological capacity of the mother to respond to her foetus^{5,6}. We reported previously that T lymphocytes taken from cord blood of human newborns inhibits their own mothers' lymphocytes from entering mitosis^{6,7}. We have studied the subpopulations of T lymphocytes in human cord blood and ascertained their ability to inhibit both the division of lymphocytes and the production of immunoglobulin by lymphocytes obtained from the mother. We report here that active T suppressor cells occur in cord blood, that these T suppressor cells bear IgG receptors; and that the T cells bearing IgG receptors inhibit both mitosis of and immunoglobulin production by lymphocytes from the mother.

Blood (10-30 ml) was collected in heparin from the umbilical cords of healthy, singleton human males immediately after delivery but before expulsion of the placenta. Venous blood (25 ml) was collected in heparin from their mothers' arm within 1 h after delivery and from non-pregnant females and males (ages 21-43 yr, all healthy). These blood samples were the source of lymphocytes prepared by using Ficoll-Hypaque gradients. Division of the lymphocytes into T-cell enriched and B-cell enriched fractions was as described before⁷. The T cell population was over 97% pure, and the B cell population over 94% pure as judged by uptake of neutral red dye and expression of surface immunoglobulins⁷. T lymphocytes were separated into subpopulations bearing Fc IgG receptors (T_G) or IgM Fc bearing receptor cells (T_M) using the method of Moretta *et al.*^{8,9}. The purified T_G and the T_M subpopulations each contained less than 1% contaminating cells.

To study the effects of lymphocytes from each newborn on the growth of lymphocytes from his mother, equal numbers of cells from each mother and her baby ($1-2 \times 10^6$ from each) were combined and suspended in RPMI 1640 medium containing 20% foetal calf serum, antibiotics and glutamine (RPMI growth media) with phytohaemagglutinin P (PHA-P) (50 μ g per ml of medium). This concentration of PHA-P had been found to be optimal for stimulating lymphocytes from both the mother and baby¹⁰. When kept separate, both mothers' and newborns' cells divided equally well with an average viability of 60%-80% as determined by Trypan blue dye exclusion. After incubation for 3 d the cultures were treated with colchicine and the chromosomes prepared and stained as reported before^{7,11}. Cells from a male baby (positive for

Y chromosome) were always mixed with his mother's cells (lacking a Y chromosome)

Table 1 shows that when unseparated lymphocytes or enriched subpopulation of T_G cells from a newborn baby were cultured with equal numbers of lymphocytes from his mother, the vast majority of cells undergoing mitosis were of baby origin. In all six pairs studied in which the newborn's T_G cells were mixed with his mother's lymphocytes, a mean \pm s.e.m. of $90.7 \pm 1.4\%$, whereas 9% or less were from the mother ($P < 0.01$). In contrast, when T_G depleted fractions of cells were taken from a newborn and mixed with his mother's lymphocytes, only about half of the cells undergoing mitosis were of baby origin (Table 1). Thus in all six pairs involving T_G depleted cell populations, a mean of $49.3 \pm 2.3\%$ of the total lymphocytes in mitosis were from newborns as determined by the presence of the Y chromosome (unfractionated T lymphocytes from cord blood gave a value of $90.7 \pm 1.4\%$, whereas 9% or less were from the mother ($P < 0.01$). In contrast, when T_G depleted fractions of cells were taken from a newborn and mixed with his mother's lymphocytes, only about half of the cells undergoing mitosis were of baby origin (Table 1). Thus in all six pairs involving T_G depleted cell populations, a mean of $49.3 \pm 2.3\%$ of the total lymphocytes in mitosis were from newborns as determined by the presence of the Y chromosome. When the T_M subpopulation of a newborn's cord blood lymphocytes were mixed with lymphocytes from his mother, roughly half of the cells undergoing mitosis were

Lymphocytes from newborns and their mothers were obtained after Ficoll-Hypaque gradient centrifugation. The T cells were separated from these lymphocytes by E rosetting, and then distinct subpopulations of T_G or T_M cells were isolated on the basis of binding and rosetting with ox red blood cells (RBC) bearing the Fc portion of human IgG or IgM, respectively. Briefly, purified T cells were mixed with ox erythrocytes (ORBC) coated with rabbit IgG antibodies, pelleted and incubated on ice for a minimum of 10 min. Rosetting cells (T_G) were separated from non-rosetting cells (T_G depleted fraction) and purified by pelleting through two density gradients. The collected cell suspension contained less than 1% non-rosetting cells. RBC were removed by treatment with ammonium chloride buffer and the residual lymphocytes were suspended in 199 medium supplemented with 20% foetal calf serum, antibiotics and glutamine (199 growth medium), and pelleted. T_G enriched and T_G depleted cells were then resuspended in 199 growth medium and incubated overnight. T_G depleted cells were mixed with ORBC coated with rabbit IgM antibodies, pelleted and placed on ice for 1 h. The resulting rosettes purified on a Ficoll-Hypaque gradient were dissociated in a vortex mixer and purified human IgM at a concentration of $125 \mu\text{g ml}^{-1}$ added to block free IgM receptors. T_M cells were then separated from ORBC by density gradient centrifugation. Equal numbers of cells ($1-2 \times 10^6$) from male newborns and their mothers were mixed and cultured with PHA-P, $50 \mu\text{g ml}^{-1}$. After incubation for 3 d the cells were treated with colchicine, collected and stained with quinacrine hydrochloride (to mark the Y chromosome). Usually 50-100 cells in metaphase were examined from each culture for the presence or absence of the Y chromosome. In the culture conditions used, lymphocytes from mothers survived as well as lymphocytes from newborns and mean mitotic indexes of both pairs of cells were equivalent. Mixing adult (instead of newborn) male lymphocytes with lymphocytes from mothers (or other adult females) resulted in % of metaphase cells having a Y chromosome \pm s.e.m. of $52 \pm 8\%$.

of baby origin ($53.2 \pm 2\%$). Clearly, the subpopulation of T cells that suppressed mitosis of mothers' lymphocytes is that bearing Fc receptors for IgG. Further, these studies showed that lymphocytes collected from an infant's cord blood are primed to inhibit division of the mother's lymphocytes and do not need to be activated.

We then studied the effects of subpopulations of T lymphocytes obtained from each newborn on the ability of lymphocytes from his mother to make immunoglobulin. Experiments with polyclonal B cell differentiation induced by PWM had indicated both the need of T cell help and the optimal synthesis of immunoglobulin, which usually occurred by the seventh day^{9,12}. After culturing an enriched T cell population from a newborn baby with B lymphocytes from his mother, we found that significantly less immunoglobulin was synthesised than when the enriched T lymphocytes came from the mother. Hence, in all three pairs tested (Table 2), when T cells from the newborn were mixed with B cells from the mother, a 46% or greater reduction in immunoglobulin production (average $55.3 \pm 5.8\%$) occurred. These results could be influenced, in part, by the inability of 'immature' newborn T cells to provide sufficient help for adult B cells¹³. This is not the likely explanation for our results, however, as T cells from newborns or from adults provide equivalent amounts of help for synthesis of immunoglobulin by B cells of the newborn (Table 2). That T cells from a newborn apparently could not inhibit immunoglobulin production by its own B cells is consistent with our observation that lymphocytes from a newborn baby cannot abrogate the proliferation of lymphocytes from other newborns⁷. This result suggests that the newborn's lymphocytes, themselves, resist the inhibitory action for which they are responsible. Other studies showed that the suppression of immunoglobulin production by B cells from the mother resided in the T_G subpopulation of cells obtained from cord blood (Table 3). Hence, when equivalent numbers of a newborn's T_G lymphocytes were mixed with B cells from his own mother or from an alien mother, immunoglobulin synthesis was inhibited 63% or 65%, respectively.

Cells from newborns and their mothers were placed on Ficoll-Hypaque gradients and separated into B cell and T cell populations^{7,9}. Equal numbers of B cells (1×10^6) and T cells were incubated in culture with PWM ($50 \mu\text{g ml}^{-1}$, the concentration optimal for stimulating B and T cells⁷) in 5 ml of growth medium. After 7 d the culture supernatant fluids, free of cells, were analysed for IgG concentration by measuring the ability of various dilutions of supernatant fluid to block IgG-anti IgG binding. The reagents, their purity and the methodology for doing this assay were as before^{12,16}. The lower limit of immunoglobulin detection was 4 ng of IgG per ml. ND, none detected.

These results clearly show that T lymphocytes bearing Fc receptors for IgG (T_G) taken from the cord blood of human male newborns effectively suppress the division of their mothers' lymphocytes and lower the ability of B cells from the mother to make IgG *in vitro*. In contrast, the T-cell enriched lymphocyte population taken from human cord blood, then either depleted of T_G cells or bearing only IgM receptors (T_M) cannot suppress mitoses of maternal lymphocytes. These data are consistent with and extend the results of Moretta *et al.*, who showed that T_G lymphocytes obtained from adults dose-dependently suppressed

Table 3 T_G subpopulation of T lymphocytes from the human newborn suppresses production of immunoglobulin by lymphocytes of its mother

Mother: BA	Newborn: WE	T _G	108	65

Adult human peripheral blood or cord blood placed on Ficoll-Hypaque gradients was separated into B and T lymphocyte fractions. T cells from newborns were divided into distinct populations of T_G cells on the basis of rosetting with ox RBC. 1×10^6 B cells from a mother were mixed with either 1×10^6 total T cells from the same mother or 1×10^6 T_G cells from her baby or an alien baby and cultured with PWM in 5 ml of RPMI growth medium. After 7 d the cultured supernatant fluids, free of cells, were analysed for IgG concentration (see Table 2 legend).

the differentiation and proliferation of B cells after stimulation with PWM in the presence of helper T_H cells⁹. No significant suppressor activity by peripheral blood lymphocytes collected from adults occurred unless T_G cells were first activated by interaction with immune complexes. In contrast, we found that T suppressor cells (T_G) in human cord blood are already active and able to suppress mitosis of maternal lymphocytes and production of immunoglobulin by maternal lymphocytes induced to differentiate with PWM. This indicates that lymphocytes from the baby are probably primed *in vivo* for their suppressor effect. Recently Maissin and his associates¹⁴ detected circulating antigen-antibody complexes in the sera of most pregnant women, suggesting a possible mechanism whereby T_G cells of a newborn may be activated. Further interaction of maternal and neonatal cells may generate T_G cells. Also suggestive of the biological importance of T_G cells in maternal-foetal interrelationships is the finding that three to fourfold more T_G cells are found in cord blood than in adults' blood (> 30% in the former compared with < 10% in the latter¹³).

How does this suppression work? Olding, Murgita and Wigzell using double culture chamber systems have shown that cord blood lymphocytes from a newborn effectively suppress the proliferation of lymphocytes from their mothers or other non-pregnant adults across a cell-semipermeable membrane, suggesting that inhibition of maternal lymphocyte proliferation occurs via a soluble suppressor factor(s)¹⁵. They also found that suppressor activity associated with newborn lymphocytes was completely abrogated by irradiation with 6,000 rad indicating the requirement for cell division in the *in vitro* release of suppressor factor. These findings are similar to those of Moretta *et al.*, who showed that treatment of activated T_G adult lymphocytes with 3,000 rad inhibited their ability to suppress polyclonal B cell differentiation and immunoglobulin production induced by PWM⁹.

Many factors in maternal-foetal interrelationships probably participate in preventing the automatic rejection of the foetus by its mother. Our studies suggest a mechanism by which foetal tissues can survive in a hostile immunological environment. We show that thymus derived suppressor lymphocytes, which are identified on the basis of bearing an Fc receptor for IgG, occur in infants' cord blood and perform an active process in inhibiting potentially harmful maternal lymphocytes from dividing. Further, the newborn's T suppressor cells are already primed in cord blood and after coming in contact with mothers' cells would render such cells unlikely to respond to the foetal foreign antigens. When this protective mechanism first develops is not clear, but necessarily it must arise after the foetal lymphoid system develops. The presence of foetal T_G cells late in pregnancy and their ability to release soluble suppressor factor(s) raise questions as to the level and fate of these cells during spontaneous abortions as well as the possible future use of suppressor factors as a therapeutic adjunct.

Evidence for a common evolutionary origin of gastrin and cholecystokinin

THE gastrointestinal hormones gastrin and cholecystokinin (CCK) are structurally and functionally related in that they have identical COOH-terminal pentapeptide sequences, which represent the biologically active portions of the molecules. The rest of each molecule only modifies its activity quantitatively and determines relative potencies for various targets. This has suggested that the two hormones have evolved from a common ancestral molecule^{1,2}. To test this hypothesis we have investigated the occurrence of gastrin and CCK in different vertebrate species by immunocytochemistry and radioimmunochemistry. We now present evidence that in amphibians and teleosts gastrin and CCK are no longer recognisable as separate hormones.

To avoid problems with immunocytochemical cross-reactivity, antisera specific for the NH₂-terminal and middle sequence of gastrin were prepared. In submammalian species such antisera failed to demonstrate endocrine cells, although they were potent in demonstrating mammalian gastrin-producing cells. In contrast, antisera against the common COOH-terminal sequence of the two hormones reacted well with gastrointestinal endocrine cells of mammals, birds, reptiles, amphibians and bony fishes. This suggests that the biologically active COOH-terminal sequence is the only region of the gastrin molecule that has been preserved during evolution. Hence, submammalian gastrin cells can be demonstrated only with antisera that also react with the COOH-terminus of CCK. Therefore a specific CCK antiserum (no. 4698) that reacts with sequence 25-30 of porcine CCK-33, but fails to bind any gastrin (sulphated as well as non-sulphated) was used. Thus cells reactive with the COOH-terminus-specific antiserum but not with the CCK antiserum are called gastrin cells, whereas cells reactive with both antisera can be expected to contain a region similar to sequence 25-33 of CCK-33. In this way

Fig. 1 Frog antral mucosa. Staining with CCK antiserum no. 4698 (PAP technique). Numerous immunoreactive epithelial cells are visible ($\times 280$). Specimens from gastrointestinal mucosa of mammals (man, pig and dog), birds (chicken and duck), reptiles (*Testudo graeca*), amphibians (*Rana esculenta* and *R. temporaria*) and bony fishes (*Gadus morrhua*) and from the brains of *R. esculenta* were frozen in melting Freon-22, freeze-dried, vapour-fixed with formaldehyde and embedded in paraffin. Human specimens were obtained at surgery (carcinoma) and animals were killed in slaughterhouses, by mebumal injections or by decapitation. Sections (3 μ m) were deparaffinised and subjected to indirect immunocytochemical staining for the demonstration of (1) NH₂-terminus of human gastrin-17 (antiserum no. 1295, given by Dr J. H. Walsh); (2) mid-sequence of human gastrin-17 (antiserum 4710); (3) COOH-terminus of human gastrin-17 (antisera nos 2604, 2609, 4562)^{13,14}; (4) sequence 25–30 of porcine CCK-33 (antiserum no. 4698); (5) middle region (probably sequence 19–25) of CCK-33 (antiserum no. 4478). Specificity of the antisera was ascertained using differential absorptions with: a, pentagastrin (Peptavlon, ICI); b, synthetic mid-sequence (6–13) of human gastrin-17 (given by Dr Morley); c, synthetic human gastrin-17 (SHG 1, ICI); d, highly purified porcine CCK-33 (given by Professor V. Mutt); e, synthetic caerulein (Caeruletide, given by Farmitalia, Milan). Absorptions were carried out at the optimal dilutions of the various antisera. Usually, addition of 10 μ g peptide per ml antiserum was sufficient. If the addition had no effect, the peptide concentrations were increased 10-fold. For details see refs 13 and 14. The site of antigen-antibody reaction was revealed with the peroxidase-anti-peroxidase (PAP) procedure of Sternberger¹⁵.

we ascertained that mammals (man, pig and dog), birds (chicken and duck) and a reptile (*Testudo graeca*) all contain distinct populations of gastrin and CCK cells. In these species, gastrin cells predominated in the antral mucosa whereas CCK cells occurred in the duodenum and jejunum. In amphibians (*Rana esculenta* and *R. temporaria*), however, no gastrin immunoreactive cells that did not also react with the specific CCK antiserum (no. 4698) were found (Fig. 1). CCK-immunoreactive cells predominated in the antrum but were also scattered in the small intestines. No CCK-immunoreactive cells that did not also react with the COOH-terminus-specific antisera were found. Absorption controls showed that, in all species, staining with the CCK antiserum (no. 4698) was abolished by pretreatment with CCK-33 or with caerulein, but was unaffected by pretreatment with even very large amounts of gastrin-17 (compare Fig. 1). Staining with the COOH-terminus-specific antisera was abolished by pretreatment with either pentagastrin, gastrin-17, CCK-33 or caerulein. Antiserum no. 4478, specific for the middle region (probably sequence 19–25) of CCK-33 and thus devoid of cross-reactivity to caerulein, stained no cells of the frog antral mucosa, whereas it was highly potent in demonstrating, for example, porcine CCK cells. Thus the compound present in the frog antral cells is dissimilar to CCK-33 in its middle region. Similar staining experiments with gastrointestinal mucosa of the teleost fish (*Gadus morrhua*) exactly reproduced the findings with amphibians, revealing a large population of

antral cells containing a region similar to sequence 25–33 of CCK-33. In the frog brain, many nerves showed the same pattern of immunoreactivity as the gastrointestinal endocrine cells. These nerves were most numerous in the hypothalamus where they converged towards the median eminence (Fig. 2).

In parallel with the immunocytochemical studies three individual extracts as well as pooled extracts of antrum and brain, respectively, from 30 frogs were subjected to gel chromatography as monitored by three assays: one specific for CCK and caerulein³, one measuring both CCK, caerulein and gastrin⁴ and one specific for gastrin⁴ (Fig. 3). As Fig. 3 shows, antral immunoreactivity eluted in three major peaks. The position of the peak of lowest apparent molecular size corresponded to that of caerulein. The intermediate peak eluted in a position corresponding to CCK-33 and gastrin-34 (big gastrin), whereas the size of the largest component corresponded to gastrin component I⁵ and a large CCK-component previously detected in extracts of porcine jejunum³. The immunoreactivity of the brain extracts also eluted in three major peaks in positions identical to those of the antral extracts. The smallest component, however, predominated in the brain extracts (Fig. 3). Gel chromatography of extracts of teleostean antrum and brain also revealed three immunoreactive peaks of which the quantitatively largest in the antral as well as in the brain extracts eluted in a position corresponding to caerulein.

Our data indicate that the three major components found in frog brain and antrum all contain a sequence similar to region 25–33 of CCK-33 and that the frog has no separate gastrin and CCK components. Gastrin immunoreactivity has been reported in the amphibian gastrointestinal tract⁶. Although no data concerning possible CCK immunoreactivity were given, the gel chromatographic data⁶ suggests that the peaks observed correspond to some of the components presented here.

The decapeptide caerulein and the nonapeptide phyllocaerulein, both isolated from frog skin, have important gastrointestinal actions^{7,8}. In the frog, caerulein is a much more potent stimulator of gastric acid secretion than is gastrin-17 (ref. 9). Studies with synthetic analogues have

Fig. 2 Frog median eminence. a, Staining with CCK antiserum (no. 4698), PAP technique. Numerous dark-stained fibres and dots occur in the vicinity of vessels. b, Adjacent section to (a), for comparison stained with an antiserum against the growth hormone-release inhibiting hormone, somatostatin. The distribution of the somatostatin-containing nerves is similar but not identical to that of the CCK-immunoreactive nerves ($\times 256$).

Fig. 3 Elution diagram of gastrin-CCK-like immunoreactivity in extracts of antrum and brain of the frog, *Rana esculenta*. Both individual antra and brains as well as pools of antrum and brains from 30 frogs were frozen immediately in liquid nitrogen and stored at -70°C . Brains and antra were minced while frozen and boiled for 30 min in water (10 ml per g tissue). After homogenisation, the immunoreactivity of the supernatant was measured by three assays. (1) The first was CCK-assay involving antiserum no. 4698 (raised against partially purified porcine CCK-33, final dilution 1:20,000) and ^{125}I -CCK-33. This antiserum does not bind any of the known gastrins (sulphated or nonsulphated). With caerulein as standard, this assay measures 0.3 μg Eq per g cerebrum and 1.3 μg Eq per g antrum (wet weight). The second was an assay involving antiserum no. 2720 (ref. 4) (raised against synthetic human gastrin-17, final dilution 1:150,000) and ^{125}I -gastrin-17. The antiserum binds CCK-33 with a molar potency of 0.2 compared to gastrin-17. With synthetic human gastrin-17 as

standard, this assay measures 0.2 μg Eq per g cerebrum and 0.3 μg Eq per g antrum (wet weight). The third was a gastrin-assay involving antiserum no. 2604⁴ (raised against synthetic human gastrin-17, final dilution 1:200,000) and ^{125}I -gastrin-17. The antiserum binds CCK-33 with a potency of 0.002 compared to gastrin-17. With synthetic human gastrin-17 as standard, this assay measures 9.2 ng Eq per g cerebrum and 4.3 ng Eq per g antrum (wet weight). Antral and cerebral extracts were subsequently applied to Sephadex G-50 superfine columns (11 \times 1000 mm) eluted at 4°C with 0.02 M veronal, pH 8.4, containing 0.1% bovine serum albumin. The columns were eluted at a flow rate of 3.6 ml per h and fractions of 1.0 ml were collected. The immunoreactivity of each fraction was measured by the three assays. The columns were calibrated in separate gel filtrations with ^{125}I -albumin for indication of void volume (V_0), highly purified porcine CCK-33 ($V_{\text{CCK-33}}$), synthetic caerulein ($V_{\text{caerulein}}$) and $^{22}\text{NaCl}$ for indication of the total volume of the column (V_t). The extracts were also applied to Sephadex G-25 fine columns (15 \times 90 mm) eluted at 4°C with 0.25 M NH_4HCO_3 , pH 8.2, calibrated with the same markers as the Sephadex G-50 columns. Fractions of 1.0 ml were measured by the three assays. The data are not shown in the figure because they agreed with results obtained on Sephadex G-50 columns. They revealed also three major peaks in both antral and cerebral extracts. The first peak appeared in the void volume, the second was eluted immediately after the void volume (K_{av} : 0.19) and the third was eluted after the salt peak (K_{av} : 1.21) in a position identical to that of caerulein. Extracts of pools from 15 antra and hypothalami of the teleost *Gadus morrhua* were treated exactly as frog brains and antra. Samples of 0.25 g teleost hypothalamus and 1.89 g teleost antrum were cut in small pieces in the frozen state and extracted as described here. Using the three assays, the following quantities of CCK-gastrin-like immunoreactivity were measured: (1) 108 ng Eq caerulein per g hypothalamus and 106 ng Eq caerulein per g antrum (Ab 4698); (2) 34.5 ng Eq gastrin-17 per g hypothalamus and 25.2 ng Eq gastrin-17 per g antrum (Ab 2720); (3) 1.7 ng Eq gastrin per g hypothalamus and 4.9 ng Eq gastrin-17 per g antrum (Ab 2604). By gel filtration on Sephadex G-50 superfine columns as described here, the immunoreactivity of both the cerebral and the antral extracts was eluted in three major peaks of which the quantitatively largest in both extracts occurred in a position corresponding to that of caerulein.

shown that in amphibians, in contrast to mammals, the occurrence of a sulphated tyrosyl-group in position 7 (as counted from the COOH-terminus), and not in position 6 as in gastrin (Table 1), is very important for acid stimulatory potency⁹. Thus, physiological evidence alone suggests that caerulein-like molecules are frog 'gastrins'. Our demonstration of a molecule with the size and immunological properties of caerulein in frog antrum tends to support this view. It is interesting that examination of the amino acid sequences of caerulein and phyllocaerulein shows that whereas these peptides resemble CCK in most of their sequence, they have similarities to gastrin in both their NH_2 - and COOH-terminal portions (Table 1). Thus, whereas in mammals, birds and reptiles CCK- and gastrin-like molecules occur in separate cell systems, the same cell seems to be responsible for the production of gastrin-CCK-like molecules in amphibians and bony fishes. Although comparisons with hormones of phylogenetic ancestors are impossible, the observations in frog as well as teleost antrum suggest that gastrin and CCK have evolved from a common caerulein-like ancestral molecule. Immunocytochemical studies have revealed cells reactive with antisera against caerulein as well as glucagon in cyclostomes¹⁰. Although the question whether the glucagon and caerulein-like immunoreactivity resides in a single molecule remains to be resolved, it is possible that the two main

families of gut hormones evolved from a single precursor occurring in very primitive vertebrates.

CCK-like peptides have been demonstrated in the brain of mammals^{11,12}. It is interesting that similar molecules exist in the brains of amphibians and fishes and that they have the same characteristics as the peptides found in the

gastrointestinal tract and skin. Immunocytochemical studies in frogs show that nerves containing these peptides are concentrated in the median eminence of the hypothalamus in much the same pattern as nerves containing known releasing or inhibiting factors to the pituitary (Fig. 2).

Gonadotrophin-releasing hormone deficiency in a mutant mouse with hypogonadism

FAMILIAL hypogonadism in man, due to an isolated deficiency of gonadotrophin secretion, has been well documented¹⁻⁶, but difficult to investigate because of the lack of a suitable animal model. We report here the genetic and endocrinological background of a mutant strain of mouse in which the testes and ovaries fail to develop postnatally. The primary cause of this seems to be a deficiency in hypothalamic gonadotrophin-releasing hormone (GnRH) with a consequent reduction in pituitary content and circulating levels of luteinising hormone (LH) and follicle-stimulating hormone (FSH). By analogy with the Brattleboro rat (genetic defect in vasopressin synthesis) this mutant should prove useful for studying the synthesis of hypothalamic releasing hormones as well as the role of the hypothalamic-gonadotrophin system in sexual differentiation, puberty, folliculogenesis and spermatogenesis. The mutant has been named hypogonadal, symbol *hpg*.

The mutation was found at Harwell, segregating out from matings between three pairs of full sibs. Each of these was heterozygous for the Robertsonian translocation, Rb(1.3)1Bnr, which is of tobacco mouse (*Mus poschiavinus*) origin; and the matings represented the final step of establishing the translocation on a house mouse genetic background after 10 generations of backcrossing. The house mouse used throughout the crosses was the F₁ hybrid between two inbred strains, C3H/HeH and 101/H. Since the mutation has not been found in either inbred strain, or in the original mixed tobacco mouse/house mouse stock⁷ which carried the translocation, we have concluded that the mutation must have arisen in one of the animals of the latest backcross generations.

Breeding records generally indicated an autosomal recessive inheritance. Thus, *hpg* mice (both male and female) segregated out from matings that produced the mutant in accordance with the 25% expectation for this mode of inheritance (Table 1). In addition, all animals (both male and female) that were capable of producing *hpg* offspring in intercrosses, failed to do so when tested

in outcrosses to unrelated mice. When the progeny of such outcrosses were mated together, 7 out of 22 pairs again produced the mutant. This frequency is not significantly different from the 25% expected if *hpg* is inherited as an autosomal recessive. The only evidence discordant with this form of inheritance was the apparent low frequency of heterozygotes from matings that had been shown to be capable of producing the mutant. Two-thirds of the phenotypically normal progeny of such matings should be heterozygotes and, since they cannot be distinguished from their homozygous normal siblings, the expectation of two heterozygotes being mated together in random intercrosses should be 0.44. In fact, although at

Table 1 Segregation of *hpg* among 17 matings producing the mutant

Normal ♀♀	Mutant ♀♀	Progeny			
		NC ♀♀	Normal ♂♂	Mutant ♂♂	NC ♂♂
219	55	35	197	69	14

NC, Not classified for *hpg*; this includes only pre-weaning loss for males but both pre- and post-weaning loss for females.

least 20 offspring were checked per mating, only 10 out of 47 intercrosses of this origin were capable of producing *hpg* offspring. This is significantly different from the expectation. The reason for this discrepancy is not understood.

The segregation of the Robertsonian translocation in matings producing *hpg* has not been followed, but many of the animals used in the early crosses have proved to be chromosomally normal. There is therefore little possibility that *hpg* is linked to Rb(1.3)1Bnr, and this virtually rules out the proximal regions of chromosomes 1 and 3 as the location of *hpg* in the linkage map. No other mutants similar to *hpg* and, therefore possibly allelic, are yet known in the mouse.

Hypogonadal males can readily be distinguished from their normal male siblings by external examination. The penis is smaller than normal, the scrotum is undeveloped and the anogenital distance is much shorter than in normal males. Internally, all male reproductive organs are present

Fig. 1 a, Micrograph of ovary of 71-d-old normal female at same magnification as b. Well developed follicles and a corpus luteum can be seen. b, Micrograph of ovary of 71-d-old *hpg* female. None of the follicles shows any obvious signs of antrum formation. In most cases, the oocyte is surrounded by two layers of granulosa cells. c, Micrograph of testis of 71-d-old normal male at same magnification as in d. Here, spermatogenesis is complete, and the interstitial tissue is abundant and active. d, Micrograph of testis of 71-d-old *hpg* male. The failure of full development of spermatogenesis and the undeveloped state of the interstitial cells can be seen.

Table 2 Change of organ weight (mg) with age in normal and *hpg* mice of both sexes

Males	Age (d)	Testes		Seminal vesicles		Adrenal glands	
		Normal	Mutant	Normal	Mutant	Normal	Mutant

Means based on 3-10 animals per group, unless indicated by number in parentheses.

but immature. The testes, located in the abdomen, are very small.

The effect in females is similar. Externally, *hpg* females resemble normal females but can be distinguished with reasonable accuracy by the failure of the vagina to open fully. Internally, a thread-like uterus can be seen, and the ovaries are so small as to be distinguished only with difficulty.

Groups of three to ten normal and *hpg* mice of both sexes were killed at different ages, and body, gonadal, accessory sex organ and adrenal weights were recorded.

showed early stages of antrum formation (Fig. 1b). No luteal tissue was seen and interstitial tissue seemed to be atrophic.

Tables 3 and 4 show that the pituitary content of LH and FSH was markedly reduced in the mutant, although still assayable; the levels of hypothalamic GnRH were exceedingly low or undetectable. That the hypogonadotropism/hypogonadism is due primarily to a lesion involving GnRH synthesis was supported by the fact that plasma LH could be increased in *hpg* mice by injecting synthetic GnRH intravenously, but not by electrically

Table 3 Hypothalamic GnRH, pituitary and plasma gonadotrophic hormone levels during development in normal and *hpg* males

112-115	2,230 ± 251	12 ± 2	2,207 ± 549	109 ± 20	26,498 ± 6690	402 ± 76	—	—

GnRH was measured according to the procedures outlined in refs 10 and 11; gonadotrophins were measured according to the procedures outlined in refs 11-13. For each hormone, preliminary studies demonstrated parallelism between inhibition of binding curves produced by serial dilutions of the unknown and the appropriate standard. Standards were synthetic GnRH (ICI), NIH LH-S18, and NIAMD rat FSH-RPI. Means based on 3-10 animals per group unless indicated by number in parentheses.

Table 2 shows that the development of the testes, seminal vesicles, ovaries, and uteri of the normal mice contrasts with the total lack of change with age in the *hpg* animals.

Histological examination of the *hpg* testes revealed that in the majority of seminiferous tubules, spermatogenesis was rarely advanced beyond the diplotene stage. Interstitial tissue was scanty and appeared to be inactive (Fig. 1d). The ovaries contained mainly undeveloped follicles, and the majority of follicles which had undergone growth seemed to be arrested at the pre-antral phase; a few

stimulating the hypothalamus.

A number of parameters have been examined to determine whether other hypothalamo-hypophysial systems are affected in the *hpg* mutant. Body weights (g) of *hpg* females were similar to those of their normal female sibs either at 3 weeks of age (10.54 ± 0.13 , $n=19$ compared with 10.46 ± 0.66 , $n=63$) or at 6 weeks of age (19.51 ± 0.16 , $n=19$ compared with 19.80 ± 0.6 , $n=63$). Although *hpg* males were no smaller than their normal male sibs at 3 weeks of age (10.09 ± 0.16 , $n=26$ compared with

Table 5 Pituitary prolactin and ACTH in adult normal and *hpg* animals of both sexes

	Male		Female	
	Normal	Mutant	Normal	Mutant
Pituitary prolactin (ng/pit.)	141.6±16.0	54.7±9.7	269.8±89.3	92.3±6.6
Pituitary ACTH (ng/pit.)	147.4±24.3	73.6±14.2	94.0±8.7	87.4±4

Prolactin and ACTH were measured using the NIAMD rat assay kit and the method described in ref. 11, respectively. The standards were NIAMD rat prolactin-RP1 and III IWS ACTH (Mill Hill, London, UK). Means based on 5–8 animals per group.

9.85±0.12, *n*=51), by 6 weeks of age, however, they were significantly smaller (17.77±0.22, *n*=23 compared with 22.69±0.10, *n*=51), and their body weights more closely approximated those of their normal female siblings (19.80±0.06, *n*=63). This probably reflects a difference between the two groups in testosterone secretion, if it were due to a defect in growth hormone in the mutant, a difference between body weights would also be expected to occur in the female animals.

Histological studies of the thyroids from *hpg*, and normal mice showed no obvious differences in cell height of the follicular epithelium. This suggests that TSH production may be unaffected in the mutant.

As the foetal adrenal X zone is known to disappear at puberty in the male and during the first pregnancy in the female⁸, it is not surprising that histological examination indicated its presence in *hpg* males, and in both *hpg* and normal virgin females. As there was no significant difference in the width of the zona fasciculata/reticularis between mutant and normal males and females, adrenal function in the mutant would seem to be normal. There were, however, significant intergroup differences in pituitary adrenocorticotrophic hormone (ACTH) and prolactin content in the older animals (Table 5). Although we cannot exclude partial defects in the hypothalamo–ACTH and hypothalamo–prolactin axes, these differences probably reflect the effect which the hypothalamic–pituitary–gonadal system exerts on the other systems⁹.

Gross examination of the *hpg* mice has revealed no associated central nervous or cranio–facial abnormalities. This, together with the genetic findings, suggests that the mutant is akin to Ewer's series of human subjects³ who had familial monotrophic pituitary insufficiency transmitted as an autosomal recessive.

Nigral and striatal dopamine release under sensory stimuli

SEVERAL groups have demonstrated the presence of a dopamine (DA)-sensitive adenylate cyclase in the substantia nigra. This adenylate cyclase is associated with postsynaptic dopaminergic receptors^{1–3}, supporting the hypothesis of a dendritic release of DA originally suggested by Björklund and Lindvall⁴. Other reports provided further arguments in favour of this hypothesis. Exogenous ³H-DA, taken up in slices of the rat substantia nigra, was shown to be released by potassium through a calcium-dependent process⁵. Furthermore, spontaneous and evoked release of ³H-DA has been demonstrated *in vivo* in the cat substantia nigra⁶. The increase of ³H-DA release in the substantia nigra induced by amphetamine (10^{–6} M) or benztropine (10^{–6} M) is associated with a reduction of the transmitter release from nerve terminals in the ipsilateral caudate nucleus, suggesting a decreased activity of the nigrostriatal dopaminergic⁷ neurones. A similar phenomenon was seen in the caudate nucleus when DA (10^{–7} M) was directly introduced into the substantia nigra⁸. We present here a study of the effects of unilateral sensory stimulations on the release of DA from nerve terminals and dendrites of the two nigrostriatal dopaminergic pathways. Previous studies⁹ revealed an increase in the levels of homovanillic acid in the perfusates of the cat lateral ventricle during electrical stimulation of the paws.

Groups of cats anaesthetised with halothane (2%) were implanted with four push–pull cannulae to simultaneously superfuse both caudate nuclei and both substantia nigrae using techniques detailed elsewhere^{10,11}. Purified L-3,5-³H-tyrosine (40 Ci mmol^{–1}), dissolved in an artificial cerebrospinal fluid (40 μCi ml^{–1}), was introduced in each push–pull cannula at a rate of 300 μl per 10 min using peristaltic pumps. ³H-DA released in successive 10-min fractions of superfusates was isolated from L-3,5-³H-tyrosine and ³H-metabolites by ion-exchange chromatography on Amberlite CG50 and the adsorption on alumina¹⁰. At steady-state level the quantities of ³H-DA released in the caudate nuclei and the substantia nigrae were 0.5 to 0.8 nCi per 10 min and 0.1–0.6 nCi per 10 min, respectively. They represented about 5–40 times the blank value which was identical to the counter background.

In a first experiment, a pair of electrodes was inserted into the paw of the right forelimb and a 10-min stimulation was carried out 3 h after onset of the superfusions using monophasic square pulses delivered by a Grass S 44 stimulator (4–6 V, 0.5 ms, 0.25 Hz) through a stimulus isolation unit. The intensity of the stimulus was adjusted in each experiment just below the threshold of the apparent muscle contraction. The 10-min stimulation of the paw of the right forelimb induced a significant activation (170%) of ³H-DA release in the contralateral substantia nigra when compared with the release of ³H-DA determined in corresponding fractions of control animals. This activation was associated

with a simultaneous reduction (30%) of the ^3H -transmitter release in the corresponding caudate nucleus which lasted for 1 h at least. An opposite pattern was observed in the side ipsilateral to the stimulation—the release of ^3H -DA was reduced in the substantia nigra and enhanced in the caudate nucleus (Fig. 1).

Similar results were obtained in a second experiment in which a visual sensory stimulation was substituted for the somatic electrical stimulation. In this case, the left eye was obturated and the right one was exposed for 10 min to a series of light flashes delivered with a frequency of 0.2 Hz. The two dopaminergic pathways reacted in opposite ways. In the side contralateral to the stimuli, the intense activation of ^3H -DA release in the substantia nigra was concomitant to the reduction of the ^3H -transmitter release from dopaminergic terminals and the reverse effects were seen in the ipsilateral side (Fig. 2).

The release of ^3H -DA into the substantia nigra can easily be modulated by physiological stimuli. As originally postulated⁴⁻⁶, it may originate from dopaminergic dendrites and not from recurrent axonal collaterals; the changes in the nigral release of ^3H -DA were always in the opposite direction to those observed in striatal terminals. This extends our previous data which indicated some differences in the characteristics of the release process of ^3H -DA in the substantia nigra and in the caudate nucleus⁶. Indeed, tetrodotoxin, a neurotoxin which blocks sodium channels, did not reduce the release of ^3H -DA in the substantia nigra in

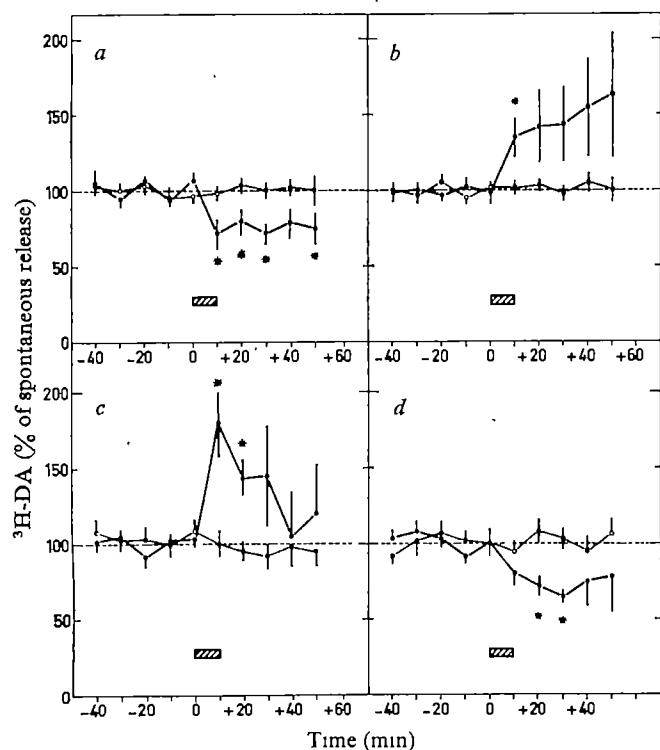

Fig. 1 Effects of unilateral somatic electrical stimulation on the release of ^3H -dopamine from the two caudate nuclei and the two substantia nigrae. Four push-pull cannulae were simultaneously implanted in the left (a) and the right (b) caudate nuclei and in the left (c) and the right (d) substantia nigrae. The four structures were perfused with an artificial cerebrospinal fluid containing L-3,5- ^3H -tyrosine. ^3H -dopamine was estimated in 10-min successive superfuse fractions. The paw of the right forelimb was stimulated (hatched bars) for 10 min using a pair of electrodes (monophasic square pulses, 4–6 V, 0.5 ms, 0.25 Hz). In each animal and for each cannula, ^3H -dopamine in each successive fraction was expressed as a percentage of an average spontaneous release calculated from the five fractions collected before the stimulation. Data are the mean \pm s.e.m. of results obtained with five animals (a, b) or four animals (c, d). *, $P < 0.05$ when compared with corresponding control values (○) obtained in five non-stimulated animals.

Fig. 2 Effects of unilateral visual stimulation on the release of ^3H -dopamine from the two caudate nuclei and the two substantia nigrae. Animals were treated as described in Fig. 1, except that the peripheral stimulation consisted of a series of light flashes (10 min, 0.2 Hz) directed to the right eye during the obturation of the left one. Data are calculated and expressed as in Fig. 1. *, $P < 0.05$ when compared with corresponding control values (○) obtained in five non-stimulated animals. a, Left, and b, right caudate nuclei. c, Left, and d, right substantia nigrae. Results for a–d are from five animals.

contrast to that observed in the caudate nucleus.

In the side contralateral to the somatic or visual stimulation, the activation of the dendritic release of ^3H -DA was always associated with a decreased activity of the dopaminergic neurones as indicated by the reduction of the transmitter release from nerve terminals. This phenomenon can be compared with the reduction of the activity of these neurones induced by the nigral application of DA⁴ (10^{-7} M), amphetamine⁷ (10^{-6} M) or benztropine⁷ (10^{-6} M), treatments which enhance the synaptic levels of the amine in the substantia nigra⁶. It may be related to the presence of autoreceptors on dopaminergic cells, first suggested on the basis of electrophysiological studies¹². Therefore in physiological states, it can be postulated that the activity of the dopaminergic neurones is inversely correlated to the extent of the dendritic release of the transmitter.

In a previous study¹³, we demonstrated the occurrence of a reciprocal control of the activity of the two nigrostriatal dopaminergic pathways. Briefly, treatments which selectively reduced the activity of one nigrostriatal dopaminergic system activated the release of DA from the nerve terminals of the contralateral dopaminergic neurones. This was observed shortly after the electrocoagulation of the left substantia nigra and during its superfusion with DA (10^{-7} M), amphetamine (10^{-6} M) or benztropine (10^{-6} M). In these experimental conditions, the existence of opposite changes in the release of ^3H -DA from the nerve terminals of the two caudate nuclei was confirmed. If, as already discussed, the activity of the dopaminergic neurones is dependent on the extent of the dendritic release, it can be assumed that the opposite fluctuations in ^3H -DA release from nerve terminals are related to the reverse opposite

changes in the transmitter release occurring at the substantia nigra level.

In our initial demonstration of the reciprocal control of the activity of the two dopaminergic pathways¹³, the opposite changes in activity of these systems were triggered by physical or pharmacological manipulations of the dopaminergic neurones in one substantia nigra. Therefore, the marked opposite variations in the activity of the two systems seen under unilateral sensory stimulation could be initiated by inputs preferentially delivered on one pathway. But, nearly identical evoked potentials have been recorded in the two substantia nigrae during unilateral stimulation of the limbs¹⁴. Similarly, bilateral responses were also found in the caudate nuclei during unilateral somatic stimulation or unilateral visual stimulation¹⁵. The neuronal circuits involved in the opposite changes in the activity of the two dopaminergic pathways are not known, however.

Our results support the concept of the involvement of the nigrostriatal dopaminergic neurones in the integration of multisensory inputs¹⁶. In fact, unilateral degeneration of the ascending dopaminergic neurones is known to produce a pronounced deviation in movements and posture on the side ipsilateral to the lesion and a pronounced deficiency in the ability to orientate toward sensory stimuli which are presented to the contralateral side of the body¹⁶. The demonstration of the dysmetric activity of the two dopaminergic pathways in response to unilateral sensory information should be of heuristic value for the understanding of the role of the extrapyramidal system in sensory motor integration.

Chlordiazepoxide selectively augments GABA action in spinal cord cell cultures

THE clinical actions of benzodiazepines—relief of anxiety, suppression of convulsions, and relaxation of skeletal muscle—suggest that they enhance inhibition in the central nervous system (CNS) but their mechanism of action is unknown. Indirect evidence^{1,2} indicates that benzodiazepines augment the action of γ -aminobutyric acid (GABA), a putative inhibitory transmitter. For example, diazepam increases presynaptic inhibition in the spinal cord^{3,4}, a type of inhibition that may reflect GABA action on primary afferent terminals⁵.

In addition, chlordiazepoxide mimics GABA in decreasing the firing rate of rat brain neurones⁶. These, and other, actions of benzodiazepines are blocked by the GABA antagonists, picrotoxin and/or bicuculline. Precise interpretation of such indirect evidence is difficult in view of the complexity of the intact brain, and the picture is far from clear. One physiologic study has concluded that benzodiazepines are potent GABA antagonists⁷. Another study based on benzodiazepine displacement of ³H-strychnine binding to CNS membranes suggested that these drugs may interact with glycine receptors rather than GABA receptors⁸. We have analysed the effect of chlordiazepoxide (CDPX) on GABA and glycine responses in spinal cord cell cultures, where individual neurones can be visualised and tested directly. Our results suggest that CDPX selectively facilitates the action of GABA, whether exogenously applied or synaptically released, by a direct action on the postsynaptic membrane.

Cells were dissociated from 4–7-d embryonic chick spinal cords, and plated in collagen-coated 35-mm tissue culture dishes, as previously described⁹. Electrophysiologic experiments were performed on the stage of an inverted microscope equipped with phase-contrast optics. The cells were perfused with oxygenated nutrient medium and temperature (34–36 °C) and pH (7.4) were carefully controlled. Individual neurones were penetrated for intracellular recording with 4 M potassium acetate or 3 M potassium chloride filled microelectrodes ($R = 50$ –100 M Ω). Membrane conductance was monitored by injecting pulses of inward current through the recording electrode (connected in a bridge circuit). Drugs were applied by pressure ejection from blunt tip (3–5 μ m) pipettes; this technique allows application of known drug concentrations. GABA and glycine were also applied by iontophoresis from fine tip (< 0.5 μ m) double barrel pipettes.

Recordings were taken from over 200 cells studied 11–40 d after plating. The cell bodies of neurones selected ranged between approximately 20 μ m and 50 μ m in diameter. All neurones tested were sensitive to GABA and glycine. Both drugs were applied sequentially to 38 cells. With a potassium acetate electrode, and a good penetration (resting potential -70 mV to -80 mV), application of either drug produced a small depolarising response associated with a marked increase in membrane conductance.

Fig. 1 GABA and glycine (Gly) responses. *a* and *b* are slow-speed tracer records of responses to pressure ejected GABA (1 mM) and glycine (1 mM). Horizontal lines below the records indicate the pressure pulse duration. Vertical lines are electronic potentials produced by inward current pulses (1 nA for 100 ms in *a*, 0.26 nA for 100 ms in *b*): their length is proportional to the cell input resistance. In (*a*) the cell was penetrated with a potassium acetate electrode, and GABA and glycine responses were evoked at two membrane potentials (note the vertical scale). Both responses reversed polarity at about -60 mV. *b* shows responses recorded in another cell with a potassium chloride electrode. After Cl^- loading, both drugs depolarised the cell to about -10 mV. Baseline irregularity in these and other records reflect spontaneous synaptic activity. *c* and *d* are oscilloscope traces showing fast GABA and glycine responses (potassium chloride recording electrode) following iontophoresis from a double barrel pipette. Iontophoretic current pulses are shown below each trace. The paired responses were evoked before (left), during (middle) and 1 min after (right) pressure ejection of the indicated antagonists. The voltage calibration bar also indicates 0.4 μ A in *c* and 1.0 μ A in *d*. Bicuculline was added at 2.2×10^{-4} M and strychnine at 10^{-5} M.

These voltage responses reversed direction when the cell was depolarised above -50 mV to -60 mV (Fig. 1a). As expected from work in other systems (for review see ref. 10), the increase in membrane conductance induced by GABA or glycine reflects primarily an increase in permeability to Cl^- ions. When KCl filled recording electrodes were used, the reversal potential for both drugs was shifted towards 0 mV (Fig. 1b). Pressure ejection of bicuculline or strychnine attenuated GABA and glycine responses, respectively (Fig. 1c, d).

Pressure ejection of CDPX immediately produced a striking potentiation of the GABA response, while having no effect on the glycine response (Fig. 2a). The potentiation was rapidly reversible after termination of the CDPX pulse, but it was maintained for

Fig. 2 CDPX potentiation of GABA responses. In *a*, paired iontophoretic glycine and GABA responses are shown on a slow speed tracer (top). Note the selective potentiation of the GABA potential. The same phenomenon is shown in fast oscilloscope sweeps (below) taken before, during and after pressure ejection of CDPX ($60 \mu\text{M}$). Note that different sets of calibration bars apply to top and bottom records. The late depolarisation seen here subsequent to CDPX application (top) probably reflects potentiation of GABA that leaks from the closely applied iontophoretic pipette. It was never observed in the absence of a GABA pipette. *b*, A trace illustrating that potentiation of submaximal GABA responses depends on CDPX concentration. $6 \mu\text{M}$ GABA was applied by pressure ejection at the indicated times. The small hyperpolarisation coincident with CDPX ejection is an artefact. Spontaneous synaptic potentials were suppressed in this experiment with tetrodotoxin ($3.4 \times 10^{-8} \text{ M}$). The break in the record represents a 2-min interval. *c*, Trace illustrating that a maximum (1 mM) GABA response is prolonged by CDPX (10^{-4} M) but the peak potential change and conductance increase are unchanged. Break in baseline, 4 min. Inward current pulses, 0.6 nA for 100 ms in *b*; 0.3 nA for 100 ms in *c*. Calibration bars in *a* (top) apply also to *b* and *c*. Potassium chloride recording electrode was used in *a*; potassium acetate in *b* and *c*.

several hours in the continued presence of CDPX. CDPX alone, at potentiating concentrations (10^{-7} M to 10^{-4} M), had no effect on the resting membrane potential or membrane conductance. Potentiation of GABA responses increased with increasing CDPX concentration between 10^{-7} M and 10^{-4} M (Fig. 2b), with an ED_{50} (50% effective concentration) of approximately $5\text{--}10 \mu\text{M}$ (44 cells). (The conductance caused by GABA was calculated assuming a shunt was inserted in parallel with the resting membrane conductance, and the CDPX potentiation was expressed as a percentage increase in this specific GABA conductance.) The CDPX pulse preceded the GABA pulse (Fig. 2b), so the effective CDPX concentration probably is lower than the pulse concentration, and these estimates of the ED_{50} must be considered upper limits. CDPX increased the magnitude of submaximal GABA responses.

The response to a maximal dose of GABA (1 mM) was prolonged, but the peak response was unchanged (13 cells) (Fig. 2c).

CDPX potentiation of GABA chemosensitivity might be due to: (1) blockade of GABA uptake; (2) induction of GABA release; or (3) a direct effect on the postsynaptic membrane. Blockade of uptake is unlikely. Our transport studies failed to demonstrate an effect of 1 mM CDPX on ^3H -GABA uptake in sister cultures. Also, 1 mM L-2,4-diaminobutyric acid, a known inhibitor of neuronal GABA uptake¹¹, did not alter the potentiating effect of CDPX (five cells). Induction of GABA release cannot account for the potentiation of large GABA responses in the absence of a GABA-mimetic effect. A direct postsynaptic effect on GABA receptors is most likely. Since CDPX at potentiating concentrations is not an agonist, it is probably not acting at the GABA binding site. It may bind to a regulatory site on or near the GABA receptor, and alter either the affinity of the receptor for GABA, or the coupling between GABA binding and opening of membrane chloride channels. This conclusion is consistent with a recent description of saturable, high affinity binding of ^3H -diazepam in rat brain¹². The ^3H -diazepam binding could not be inhibited by GABA or GABA antagonists.

In addition to potentiation of exogenously applied GABA, CDPX augments synaptic potentials that are probably mediated by GABA. Synaptic potentials were evoked by extracellular stimulation of nearby neurones or nerve processes, and KCl recording electrodes were used to convert small inhibitory potentials into large depolarising responses. Large Cl^- dependent synaptic potentials that were attenuated by bicuculline were augmented by CDPX (six cells) (Fig. 3). As expected of a drug which increased GABA-ergic inhibition, CDPX often reduced the overall frequency of spontaneous synaptic potentials.

Fig. 3 CDPX potentiation of a bicuculline sensitive synaptic potential. The stimulus evoked synaptic potentials labelled 1–5 were recorded with a potassium chloride electrode and were obtained in sequence. 1, Control; 2, during ejection of 10^{-4} M bicuculline; 3, return to control 1 min later; 4, during ejection of $1.2 \times 10^{-4} \text{ M}$ CDPX; 5, return to control. The stimulus artefact appears as a break in the trace immediately before the evoked response. Spontaneous synaptic potentials appear late in the records. Each record is the superposition of three consecutive oscilloscope sweeps.

This demonstration of potentiation of GABA-ergic synaptic potentials as well as of exogenously applied GABA supports the hypothesis that some central actions of benzodiazepines are associated with enhanced GABA-ergic inhibition. We found no evidence for interaction with glycine receptors. It should be noted that the CDPX ED_{50} for GABA potentiation ($5\text{--}10 \mu\text{M}$) is at least 20 times smaller than the ED_{50} reported⁸ for ^3H -strychnine displacement ($200 \mu\text{M}$). In any case, the selectivity of CDPX, as a complement to the GABA antagonists, should prove useful in identifying and characterising GABA-ergic pathways in the CNS.

Phosphorylation of chloroplast membrane polypeptides

ILLUMINATION of chloroplast thylakoids leads to the formation of the so-called high energy state of the membrane¹⁻³. The establishment of this state is accompanied by several structural changes within the membrane, including a conformational change in the coupling factor⁴, increased accessibility of photosystem II to the chemical probe *p*-diazonium benzene sulphonate⁵, and a reduction in the thickness of the partition between stacked thylakoids⁶. I describe here a rather different type of structural change that has not previously been reported for chloroplast membranes—protein phosphorylation. Like the above changes, protein phosphorylation is a reversible, energy-dependent membrane modification, but it differs from the other changes in that it takes the form of a specific chemical reaction involving certain identifiable chloroplast membrane polypeptides. The most conspicuous of these polypeptides is the light-harvesting chlorophyll *a/b* binding protein, the most abundant thylakoid polypeptide⁷.

Isolated class A or class B (ref. 8) chloroplasts of the pea (*Pisum sativum* L. var. Feltham First) incorporated ³²P-orthophosphate into ATP, CTP, GTP, UTP and RNA in the light⁹. In identical conditions of chloroplast isolation and incubation, protein phosphorylation is also readily demonstrated. After a standard incubation period of 10 min, labelled chloroplasts were washed, solubilised in boiling sodium dodecyl sulphate (SDS) solution, and fractionated by SDS-polyacrylamide slab gel electrophoresis¹⁰. Chloroplast proteins were detected by staining the gel with Coomassie Brilliant Blue (Fig. 1a) and radioactivity was located by autoradiography (Fig. 1b). Many polypeptides were visible after staining but three were particularly prominent: (1) the 54,000 molecular weight (MW) large subunit of ribulose 1,5-bis-phosphate (RBP) carboxylase, the most abundant soluble chloroplast protein¹¹, (2) the 12,000 MW subunit of the same enzyme, and (3) the 26,000 MW subunit of the light harvesting chlorophyll *a/b* binding protein complex⁷. There were two major phosphorylated polypeptides: (1) a 26,000 MW polypeptide which co-migrated in every experiment with the chlorophyll *a/b* binding protein, and (2) a 9,000 MW polypeptide whose MW was estimated by comparison with cyanogen bromide cleavage fragments derived from cytochrome *c*¹². Other phosphorylated polypeptides were also evident, their molecular weights falling generally in the

the range 7,000–70,000. Neither subunit of RBP carboxylase was labelled *in vitro*.

In many experiments, it was possible to resolve the 26,000 MW polypeptide into two labelled species (Fig. 2). The MW of the second polypeptide was estimated to be 28,000. These two polypeptides, together with the 9,000 MW polypeptide, were eluted from the gel¹³ and subjected to brief acid hydrolysis. The digestion products were separated by paper electrophoresis and shown to be phosphothreonine and orthophosphate. During acid hydrolysis phosphothreonine breaks down to threonine and orthophosphate. It is therefore likely that the 65% recovery of isotope in phosphothreonine underestimates the percentage of the label in this form in the native protein. It is possible, however, that some of the labelled orthophosphate was derived from other less stable phosphorylated amino acids such as phosphohistidine. At present, we can only say that most of the ³²P-orthophosphate incorporated into the 28,000, 26,000 and 9,000 MW polypeptides was recovered in phosphothreonine.

The 26,000 and 9,000 MW polypeptides were found to be membrane-bound and to be labelled *in vivo* (Fig. 3). The recovery of all but the 70,000 MW polypeptide in the thylakoid and envelope fraction of osmotically shocked chloroplasts indicates that chloroplast protein phosphorylation is essentially a membrane phenomenon and supports the conclusion reached earlier that RBP carboxylase was not phosphorylated *in vitro*.

Leaf pairs were allowed to take up ³²P-orthophosphate

Fig. 1 *In vitro* incorporation of ³²P-orthophosphate into chloroplast phosphoproteins. Chloroplasts from 10-d-old pea seedlings were isolated and resuspended in isotonic KCl medium as described previously^{8,10}. An aliquot (100 µg chlorophyll in 0.5 ml) was incubated at 20 °C for 10 min with carrier-free ³²P-orthophosphate (100 µCi). Illumination was by a single coil 200-W tungsten lamp (Philips). After incubation the chloroplasts were diluted with 10 ml of ice-cold 0.35 M sucrose medium containing 25 mM HEPES-NaOH buffer (pH 7.6), 2 mM EDTA and 2 mM sodium isoascorbate, and centrifuged at 2,800g for 2 min. The chloroplast pellet was washed twice in acetone-water (4:1) and then taken up in 400 µl of 2% SDS solution containing 60 mM Tris-HCl buffer (pH 6.8), 0.5% 2-mercaptoethanol and 10% glycerol. After 3 min at 100 °C, the solution was cooled and an aliquot (40 µl) was electrophoresed through a 10%–30% exponential gradient slab gel of acrylamide which included a 5% stacking gel¹⁰. The gel was stained with Coomassie Brilliant Blue, photographed and autoradiographed. *a*, Photograph of stained gel showing total chloroplast protein. *b*, Autoradiogram showing chloroplast phosphoproteins. Molecular weights were estimated by comparison with known standards, including cyanogen bromide cleavage fragments of cytochrome *c*¹².

Fig. 2 Identification of threonine as site of phosphorylation in three chloroplast phosphoproteins. *a*, Chloroplast phosphoproteins were labelled *in vitro* for 10 min, fractionated electrophoretically and located by autoradiography. *b*, Bands containing the 28,000, 26,000 and 9,000 phosphoproteins were cut from the gel slab and the polypeptides were extracted as tryptic peptides¹³. After lyophilisation the tryptic peptides were digested under N_2 in 6 M HCl (105 °C, 90 min) and analysed by electrophoresis on Whatman 3 MM paper using formic acid-acetic acid-water (1:2:45) buffer (pH 2.0). Autoradiography showed that radioactive material was located at the origin (O) and also found in phosphothreonine (PT) and orthophosphate (Pi) but not in phosphoserine (PS).

for 6 h under constant illumination and were then homogenised and chloroplasts were isolated. Electrophoresis of the solubilised polypeptides showed that the 26,000 and 9,000 MW polypeptides were again the most heavily labelled chloroplast phosphoproteins and therefore that the *in vitro* labelling of these polypeptides was not an artefact of chloroplast isolation but represented a physiological process. The broad band (X) labelled *in vivo* was phospholipid.

The *in vitro* phosphorylation of chloroplast membrane

Table 1 *In vitro* phosphorylation and dephosphorylation of chlorophyll *a/b* binding protein within isolated chloroplasts

Incubation conditions		³² P-incorporation (10 min light = 100)
Light	0 min	1
	1 min	12
	5 min	48
	10 min	100
	20 min	88
	30 min	72
	10 min + 20 μ M CCCP	1
Dark	10 min	1
Light (10 min) followed by	10 min light	88
	10 min dark	9
	10 min light + 20 μ M CCCP	20
	10 min light + 1 mM KH_2PO_4 (pH 8.3)	37

Replicate aliquots of a suspension of pea chloroplasts (100 μ g chlorophyll in 0.5 ml isotonic KCl medium) were pre-incubated for 10 min in the dark at 20 °C with or without 20 μ M CCCP. Radioisotope (100 μ Ci ³²P-orthophosphate) was then added to each replicate and incubation was continued in the light or the dark as indicated. After the incubations the chloroplasts were washed, solubilised and fractionated electrophoretically as described in Fig. 1. After the position of the chlorophyll *a/b* binding protein (26,000 MW polypeptide) had been determined by staining and autoradiography, the band of gel containing it was excised from each track and ³²P was determined by measuring Cerenkov radiation in a liquid scintillation spectrometer (counting efficiency 45%). Incorporation into the chlorophyll *a/b* binding protein is expressed relative to the incorporation into this protein after 10 min illumination (1.5×10^4 d.p.m. per gel slice, or 1.5×10^5 d.p.m. per incubation).

polypeptides was not linear with time (Table 1). Incorporation of ³²P into the 26,000 MW polypeptide was rapid for 5–10 min and thereafter was reversed. The loss of radioactivity from the 26,000 MW band was greater than could be explained by chloroplast disintegration during incubation or washing. Two processes determined the instantaneous level of protein labelling—phosphorylation and dephosphorylation. Protein phosphorylation was driven by light through photophosphorylation. In this respect it resembles RNA and protein synthesis in isolated pea chloroplasts^{14,15}. Dephosphorylation was readily demonstrated by incubating chloroplasts for 10 min in the light to label the 26,000 MW polypeptide and then subjecting the chloroplasts to various treatments to inhibit or chase protein phosphorylation: (1) dark incubation, (2) illumination in the presence of the uncoupler carbonylcyanide *m*-chlorophenylhydrazone (CCCP), and (3) a chase with 1 mM unlabelled orthophosphate. In each case, rapid loss of radioactivity from the chloroplast proteins was observed. Thus, chloroplast protein phosphorylation is reversible, being sensitive to the ATP levels within the organelle.

Chloroplast protein phosphorylation has not previously been reported, although protein kinase activity has been

Fig. 3 Location and *in vivo* labelling of chloroplast phosphoproteins. Isolated chloroplasts were incubated *in vitro* with ³²P-orthophosphate for 10 min and then washed in ice-cold sucrose medium. Half of the chloroplasts were solubilised immediately in SDS solution and the remainder were resuspended in hypotonic medium (20 mM Tris-HCl, pH 8.0, 4 mM $MgCl_2$, 2 mM 2-mercaptoethanol) and centrifuged at 30,000g for 30 min. The pellet, containing thylakoids and envelopes, was solubilised in SDS solution. Chloroplasts were also isolated from 10 leaf pairs which had taken up ³²P-orthophosphate (50 μ Ci per leaf pair) for 6 h under continuous illumination. The radioactive chloroplast pellet was solubilised in SDS solution and electrophoresed alongside the two *in vitro* labelled samples. *a*, Total chloroplast proteins, labelled *in vitro*. *b*, Total chloroplast membrane proteins, labelled *in vitro*. *c*, Total chloroplast proteins labelled *in vivo*. The broad band (X) in track *c* represents labelling in phospholipid.

attributed to chloroplasts from *Acetabularia*¹⁶ and to a fraction from *Brassica* containing nuclei and chloroplasts¹⁷. I have shown that two chloroplast membrane polypeptides (with MWs of 26,000 and 9,000) are particularly heavily phosphorylated *in vivo* and *in vitro*, with several other polypeptides also being phosphorylated to a detectable extent *in vitro*. The polypeptide of 26,000 MW co-electrophoreses with the light-harvesting chlorophyll *a/b* binding protein, the most abundant thylakoid polypeptide.

Other evidence that these two polypeptides are identical will be published elsewhere. The function of thylakoid protein phosphorylation is not known but it may be involved in establishing the high energy state of the thylakoids in state 1-state 2 transitions¹⁻³. These transitions are part of the mechanism whereby the chloroplast regulates energy flux from light-harvesting chlorophyll molecules to ensure equal electron flow through the two photosystems. This regulation may involve the binding of divalent metal cations to the chlorophyll *a/b* binding protein^{18,19}. It is likely that phosphorylation of this protein would alter both its cation binding properties and its interaction with the two photosystems.

I thank Mr N. Lengden for technical assistance and Professors W. Ogren and J. Ellis for helpful discussions.

Identification of a transformation-specific antigen induced by an avian sarcoma virus

GENETIC analyses of avian sarcoma viruses (ASV) have led to the identification of a gene, designated *src*, which encodes a product required for the initiation and maintenance of neoplastic transformation in infected fibroblasts¹⁻³. Because the *src* gene product has not been identified biochemically, this study was initiated to detect a transformation-specific protein, using serum from rabbits bearing ASV-induced tumours. We describe here the identification of a 60,000-MW transformation-specific antigen detectable in ASV-transformed chicken cells and ASV-induced hamster tumour cells by immunoprecipitation of radiolabelled cell extracts with serum from tumour-bearing rabbits. Moreover, the expression of this antigen is temperature dependent in chicken cells transformed by an ASV temperature-sensitive mutant in the *src* gene. The use of this antiserum may lead to the unequivocal identification and characterisation of the ASV *src* gene product and this, in turn, may lead to the elucidation of the mechanism of ASV-induced oncogenesis.

Serum from rabbits whose Schmidt-Ruppin (SR) strain ASV-induced tumours followed two different patterns of growth, labelled A and B and described in the legend of Fig. 1, was tested for the presence of antibodies directed against any non-structural proteins. Cell extracts prepared from radiolabelled normal and SR-ASV-transformed chicken cells were immunoprecipitated with these sera and also with monospecific sera directed against virion structural proteins, and analysed by sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis (Fig. 1). The proteins precipitated from SR-ASV-transformed chicken cells by serum A and B (tracks 5 and 7) having molecular weights (MW) of 76,000 (Pr76), 66,000, 53,000,

27,000 and 12,000-15,000 are the precursor and intermediate and mature cleavage products of the ASV group-specific (gs) antigens^{6,7}. The 180,000 MW virus-specific protein which precipitated with anti-polymerase IgG and

Fig. 1 Autoradiogram of SDS-polyacrylamide gel analysis of proteins immunoprecipitated from ³⁵S-methionine-labelled uninfected and SR-ASV-transformed chicken cells. Tumours were induced in rabbits by the subcutaneous and intramuscular injection of newborn New Zealand rabbits with ~10⁶ focus-forming units of purified SR-ASV (subgroup D). Palpable tumours appeared within 10-14 d in all of the nine rabbits injected. Tumour growth followed two different patterns involving either development of multiple metastases (serum A) or regression of the original tumours (serum B). In the experiments reported here, the serum was obtained 5 weeks after the animals had been inoculated with virus. Sera A and B were both found to contain antibodies to all three virion structural proteins including the viral core proteins or gs antigens, the envelope glycoprotein gp85, and the RNA-dependent DNA polymerase (J.S.B. et al., unpublished observations). These antibodies were detected by immunoprecipitation of ³⁵S-labelled proteins from lysed, purified ASV and by neutralisation of virion polymerase activity and of focus formation. Adult rabbits receiving the same dose of infectious virus did not develop tumours and did not produce antibody to any virus-specific proteins. Uninfected and SR-ASV-transformed chicken embryo fibroblasts (CEF) were seeded at a density of 8 × 10⁶ cells per 100-mm Petri dish and labelled the next day for 4 h with 10 μCi ml⁻¹ ³⁵S-methionine (New England Nuclear, 400 Ci mM⁻¹) in Eagle's medium lacking methionine and supplemented with 5% calf serum (Colorado Serum Co.). The cells were washed three times with STE (150 mM NaCl, 10 mM Tris-HCl, pH 7.2, 1 mM EDTA) and lysed in RIPA buffer¹¹ (150 mM NaCl, 1% sodium deoxycholate, 1% Triton X-100, 0.1% SDS, 10 mM Tris-HCl, pH 7.2) containing 1% Trasylol, a general inhibitor of proteases¹² (FBA Pharmaceuticals, New York) and centrifuged at 90,000g for 30 min. The supernatant was divided into samples of equal volume and incubated with 10 μl of the pertinent antiserum. After 30 min at 4 °C, 200 μl of a 10% suspension of the protein A-containing bacterium, *Staphylococcus aureus*, strain Cowan I were added to adsorb the immune complexes as described by Kessler¹³. After four washes with RIPA buffer, the bacteria were resuspended in sample buffer (0.07 M Tris-HCl, pH 6.8, 11.2% glycerol, 3% SDS, 0.01% bromophenol blue, 5% β-mercaptoethanol), heated at 95 °C for 1 min, pelleted, and the supernatant was electrophoresed through a discontinuous SDS-polyacrylamide slab gel system using the buffer systems described by Laemmli¹⁴. The stacking gel contained 4.2% acrylamide, 0.1% bis-acrylamide (pH 6.8). The separation gel was a 5-15% gradient of polyacrylamide (38:1 acrylamide:bis-acrylamide), 11 cm long. Gels were stained in 0.1% Coomassie blue in 50% trichloroacetic acid for approximately 1 h and destained in several changes of 10% acetic acid, 5% methanol. The dried gels were exposed to Dupont Cronex-4 medical X-ray film. Tracks 1-3 display the polypeptides immunoprecipitated from uninfected CEF with: 1, normal rabbit serum; 2, serum B; 3, serum A. Tracks 4-10 display polypeptides immunoprecipitated from SR-ASV-transformed CEF with: 4, normal rabbit serum; 5, serum B; 6, serum B which was incubated with 125 μg of purified disrupted SR-ASV before addition of the cellular extract; 7, serum A; 8, anti-RAV-0 DNA polymerase IgG; 9, anti-gp85 serum; 10, anti-p27 serum. Track 11 contains ³⁵S-methionine-labelled ASV. T7 virion proteins are included as molecular weight markers.

anti-p27 serum as well as with sera A and B has been identified as the product of genes which encode the gs antigens and DNA polymerase³. The glycoprotein, gp85, migrates on this gel with the same mobility as the viral polymerase. An additional virus-specific protein with a molecular weight of 60,000 is also precipitated by both sera. This protein is not precipitated by antibody against any of the ASV structural proteins, nor is it precipitated from normal chicken cells by any sera tested. Incubation of serum B with disrupted virus before the addition of the labelled cell extract blocks the immunoprecipitation of all the virus-specific proteins except that of the polypeptide of molecular weight 60,000 (track 6). The fact that the intensity of this antigen is identical with and without the block suggests that its immunoprecipitation is not dependent on antibodies against any of the ASV structural proteins.

Figure 2 (tracks 4, 5, and 6) displays the polypeptides immunoprecipitated from a radiolabelled extract of a cloned line of SR-ASV-induced Syrian hamster tumour cells (SR-SHC/C1A). These proteins are co-electrophoresed with immunoprecipitates from SR-ASV-transformed chicken cells (tracks 1, 2, and 3). Serum B precipitated two virus-specific proteins from SR-SHC/C1A cells. One protein co-migrates with the Pr76 precipitated from SR-ASV-transformed chicken cells (track 2). No mature gs antigens are detectable in these hamster tumour cells, which suggests that Pr76 is not processed normally. The only other virus-specific protein precipitated from this hamster tumour cell line by serum B is a protein which co-migrates with the 60K protein immunoprecipitated from chicken cells. This polypeptide is not precipitated by antibody to any structural proteins, nor is it immunoprecipitated from normal Syrian hamster cells by any sera tested. When disrupted virus is incubated with serum B before the addition of the labelled cell extract (track 6), the precipitation of Pr76 is completely blocked, whereas the intensity of the 60K band is identical to

Fig. 2 Autoradiogram of SDS-polyacrylamide gel analysis of proteins immunoprecipitated from SR-ASV-transformed chicken and hamster cells. SR-SHC/C1A cells were obtained by trypsinisation of a tumour induced by injection of a newborn Syrian hamster with SR-ASV. Cells were labelled with ³⁵S-methionine, immunoprecipitated and electrophoresed as described in the legend to Fig. 1. The cells and serum used are the following: 1, ASV-transformed CEF, normal serum; 2, ASV-transformed CEF, serum B; 3, ASV-transformed CEF, serum B blocked with 125 µg disrupted virus; 4, SR-SHC/C1A, normal serum; 5, SR-SHC/C1A, serum B; 6, SR-SHC/C1A, serum B blocked with 125 µg of disrupted virus. Track 7 contains ³⁵S-methionine-labelled ASV-virion proteins.

Fig. 3 Autoradiogram of SDS-polyacrylamide gel analysis of proteins immunoprecipitated from ³⁵S-methionine-labelled chicken cells transformed by the SR-ASV mutant NY68 (subgroup A). CEF cells were transformed with NY68 (ref. 4) and maintained at 35 °C. Transformed cells were trypsinised and plated at 35 °C or 41 °C at a density of 8×10^6 cells per 100-mm Petri dish and 16 h later the cultures were labelled for 1 h with 20 µCi ml⁻¹ ³⁵S-methionine, immunoprecipitated and analysed as described in Fig. 1. The temperature of incubation of NY68-transformed cells and the serum used for immunoprecipitation are the following: 1, 35 °C, normal serum; 2, 41 °C, normal serum; 3, 35 °C, serum B; 4, 35 °C, serum B blocked with disrupted virus; 5, 41 °C, serum B; 6, 41 °C, serum B blocked with disrupted virus; 7, 35 °C, anti-p27 serum; 8, 35 °C, anti-p27 serum blocked with disrupted virus; 9, 41 °C, anti-p27 serum; 10, 41 °C, anti-p27 serum blocked with disrupted virus. Track 11 contains ³⁵S-methionine-labelled ASV virion proteins.

that in track 5. The 60K protein is also detectable in another line of hamster tumour cells derived from a tumour induced by SR-ASV in the inbred LSH strain of hamsters.

The presence of an antigen having identical molecular weights in two different species of ASV-transformed cells suggests that this antigen is ASV transformation specific. This conclusion is supported by the finding that cells infected with a SR transformation-defective mutant or with RAV-50 or Carr-Zilber Associated virus (CZAV), both subgroup D viruses, do not contain the 60K protein. The expression of this transformation-specific antigen was also examined in cells infected with the SR-ASV temperature-sensitive (*ts*) mutant, NY68 (ref. 4) (subgroup A), which is defective in the initiation and maintenance of transformation at 41 °C, although virus replication is normal at this temperature. Figure 3 shows that the 60K protein was barely detectable in NY68-transformed cells grown at 41 °C relative to the 60K band from cells cultured at 35 °C. Equivalent amounts of the other virus-specific proteins such as the gs antigens and their precursors (180K, Pr76, Pr53, p27, and p12-15) were immunoprecipitated from cells grown at both temperatures, indicating that overall virus-specific protein synthesis at the two temperatures was the same and suggesting that the presence of the 60K protein is transformation dependent.

The use of serum from rabbits bearing ASV-induced tumours has allowed the detection of a 60,000 MW protein which has the following properties of an ASV transformation-specific antigen. (1) This protein is present in two different species of cells transformed by ASV. It seems unlikely that a virus-induced, cell-coded protein from two such widely divergent species would have identical molecular weights. Tryptic peptide fingerprints of the 60K proteins from transformed hamster and chicken cells are being prepared to characterise these

two proteins further. A 60K polypeptide has been synthesised in reticulocyte cell-free extracts using sub-genomic regions of the ASV genome as a mRNA (ref. 8). Experiments are in progress to ascertain whether it is the product of the ASV *src* gene. (2) The 60K polypeptide is not detectable in cells infected with non-transforming leukemia viruses (RAV-50 and CZAV) of the same subgroup as the tumour-inducing virus or with a SR transformation-defective virus. (3) The amount of 60K protein is greatly reduced at the non-permissive temperature in cells transformed by a mutant, NY68, temperature sensitive in the production of the *src* gene product. This suggests that the 60K protein could be the product of the mutant gene and that the polypeptide loses its antigenicity when denatured at 41 °C and is unable to react with the antibody or that the defective protein may be degraded more rapidly at 41 °C than the normal protein and thus less is detected in the conditions used here. Accelerated degradation of the protein products of *ts* genes at the non-permissive temperature has been demonstrated with mutants of vesicular stomatitis virus and of SV40 (refs. 9, 10). Alternatively, the 60K protein could be a virus-induced cell-coded protein, and its reduced immunoprecipitation at 41 °C may merely reflect host changes secondarily associated with the loss of transformation. All of these possibilities are being investigated.

We thank H. Hanafusa for the mutant ASV NY68, Satoshi Mizutani for anti-DNA polymerase IgG and D. Bolognesi for anti-gp85 serum. This work was supported by grants from the National Institutes of Health. J.S.B. was supported by an NIH Postdoctoral Fellowship.

Structures of benzo(a)pyrene–nucleic acid adducts formed in human and bovine bronchial explants

PUBLICATION by Sims *et al.* of evidence that the 7,8-dihydrodiol-9,10-oxide of benzo(a)pyrene (BP) is a metabolic intermediate in the covalent binding of this ubiquitous polycyclic aromatic hydrocarbon to DNA in hamster embryo cells¹ was followed by many related publications². Grover *et al.*³ also obtained evidence that the same derivative is involved in the binding of BP to the DNA of human bronchial explants, although details of the specific isomer involved and of the structure of the adduct were not reported. We describe here studies on RNA and DNA adducts formed by human bronchial explants and provide evidence that the structures of the major adducts are similar to those formed in the analogous bovine system.

Two stereoisomers of BP 7,8-dihydrodiol-9, 10-oxide (BPDE) have been synthesised. In isomer I, the 7-hydroxyl and 9,10-oxide groups are on the opposite sides of the plane of the ring system while in isomer II they are on the same side. Each stereoisomer has

Fig. 1 HPLC profile of RNA adducts formed by human bronchial explants incubated with ³H-BP. Human bronchial explants were incubated for 24 h with ³H-BP (ref. 20). The tissue was then homogenised with a Polytron PT 10-20-350D homogeniser in 3 ml of 10 mM Tris-HCl, 0.4 M NaCl, 2 mM EDTA (pH 7.9). Sodium dodecyl sulphate (SDS) (30 µl 20%) and proteinase K (0.5 ml, 2 mg ml⁻¹) were then added and the mixture incubated overnight to dissolve the tissue. The solution was then extracted several times with water saturated phenol containing 0.1% SDS and 0.1% 8-hydroxyquinoline and once with chloroform-ethyl alcohol (3:1) before the addition of 0.03 volumes of 2 M sodium acetate (pH 5.0) and precipitation with 2 volumes of ethanol. The ethanol precipitation was repeated and followed by the addition of 50 A₂₅₀ units of poly (G) previously modified by reaction with BPDE I (ref. 12) and then hydrolysis of the RNA in 0.3 M NaOH overnight at 37 °C. The samples were neutralised with acetic acid and chromatographed on Sephadex LH 20 columns. The DNA eluted in the void volume and the modified ribonucleotides eluted with 40% methanol. The latter were treated with alkaline phosphatase overnight before separation by Sephadex LH 20 chromatography, this time eluting with 80% methanol. The modified nucleosides were then resolved by HPLC on Zorbax ODS columns operated at 2,500 pounds per square inch at 50 °C, with 30% methanol in water for elution. Adducts resulting from the *in vitro* reaction of BPDE with poly (G) were detected by ultraviolet absorbance at 280 nm and *in vitro* samples by their radioactivity.

two enantiomers which have also been prepared^{4–6}. We have previously published the complete structure and stereochemistry of a major RNA adduct formed in bovine bronchial explants exposed to BP (refs 5, 7, 8) and shown that it is derived from the 7R,8S,9R,10R enantiomer of BPDE (designated 7R-BPDE I) by the *trans* addition of the N² amino group of guanine to the 10 position of the dihydrodiol oxide. Our assignment of the absolute stereochemistry of BP 7,8-dihydrodiol obtained during these studies has been confirmed by Yagi *et al.*⁴. Evidence that RNA (ref. 9) and DNA adducts^{10,11} are formed from both isomers I and II in other tissues and species, and that these involve the formation of similar guanine adducts, has been obtained.

After exposure of explants of human or bovine bronchial segments to ³H-BP, cellular RNA and DNA were isolated and digested to release the modified ribo- and deoxyribonucleosides. The latter were separated by Sephadex LH-20 chromatography and then analysed by high pressure liquid chromatography (HPLC) using appropriate markers synthesised *in vitro*.

Figure 1 shows the HPLC profile obtained when human RNA was digested and cochromatographed with marker nucleoside adducts formed *in vitro* by the reaction of BPDE I with poly G. The profile of the human RNA *in vivo* products is similar to that reported for bovine RNA samples⁵, although the minor products are more pronounced with the human material. The digest of human RNA revealed four distinct radioactive peaks, designated H-RNA 1–4 (Fig. 1 and Table 1). We have previously reported that BPDE I and BPDE II can form adducts *in vitro* with guanosine, cytidine and adenosine¹². Table 1 indicates that during HPLC the radioactive peaks eluted in the same region as some of these guanosine and cytidine adducts. The adenosine adducts formed *in*

in vitro elute much later and very little radioactivity was detected in this region. By comparing the elution positions, before and after acetylation, of the radioactive peaks to the elution positions of the guanosine and cytidine adducts formed *in vitro*, we could conclude that H-RNA peaks 1 and 4 coincided with 7R-BPDE I-guanosine adducts GI-2 and GI-3, respectively; H-RNA peak 3 with a BPDE II-guanosine adduct GII-2; and H-RNA 2 with a BPDE I-cytidine adduct CI-3 (Table 1). A major peak, H-RNA 4, coincides with the major bovine RNA adduct whose structure and stereochemistry has been previously elucidated^{5,7,8}. This compound results from *trans* addition of the 2 amino group of guanine to the 10 position of the 7R enantiomer of BPDE I. H-RNA I also is derived from 7R BPDE I (ref. 8) and represents the analogous compound formed by *cis* addition (unpublished results and ref. 9). The predominance of adducts derived from a specific enantiomer of BPDE I suggests that both bovine^{7,8} and human tissue oxidise BP with a considerable degree of stereospecificity. Separate studies¹³⁻¹⁵ also indicate considerable stereospecificity in the metabolism of BP. Based on elution order and identity of circular dichroism (CD) spectra ($\Delta\epsilon_{250} = -93$), peak GII-2 (Table 1) corresponds to an adduct whose structure has been previously elucidated by Koreeda *et al.*^{9,16}. It results from *trans* addition of the 2 amino group of guanine to the 10 position of 7S BPDE II. Since HRNA-3 is

Table 1 Separation of BP-nucleoside adducts and their corresponding acetates by HPLC

Compound	Retention time		Compound	Retention time	
	Nucleoside	Acetate		Nucleoside	Acetate
HRNA-1	20	21	CII-1	21	18
HRNA-2	26	23	CII-2	29	20
HRNA-3	31	34	CII-3	42	—
HRNA-4	33	37	CII-4	44	—
GI-1	18	27	CII-5	55	—
GI-2	20	21	CI-1	17	19
GI-3	33	37	CI-2	20	13
GII-1	23	23	CI-3	26	23
GII-2	31	34	CI-4	27	14
GII-3	33	28	CI-5	31	15
GII-4	58	—	CI-6	44	12

The nucleoside adducts were prepared and separated on HPLC as described in Fig. 1. Data are retention times of the human bronchial RNA (HRNA) adducts formed *in vivo*, and of guanosine (G) and cytidine (C) adducts formed *in vitro* by reaction with BPDE isomer I or II. Numbers 1, 2, 3, 4 refer to the order of elution of individual peaks from column. After elution individual peaks were acetylated (pyridine, acetic anhydride, 18 h room temperature) and re-run on HPLC using 55% methanol in water as solvent. The underlines indicate *in vitro* products which were cochromatographic with specific human RNA adducts. Further evidence for the chromatographic identity of HRNA-2 and 3 with the *in vitro* markers (CI-3 and GII-2) was obtained when their acetates were run on HPLC with 50% methanol as eluent. In these conditions slight isotopic separations were observed, similar to those previously reported²¹.

cochromatographic with GII-2 this indicates that there is some synthesis of BPDE II by human tissue.

The situation with DNA from both human and bovine samples was much simpler than with RNA. Following enzymatic digestion of the DNA samples, 80% of the modified deoxynucleosides eluted from the HPLC columns essentially as a single component, both before and after acetylation (Fig. 2). (The remaining 20% may be incompletely digested materials, since it eluted in the void volume of the Sephadex LH-20 column, and not been further characterised). With both the human and bovine material, the single radioactive peak cochromatographed with one of the deoxyguanosine-BPDE I derivatives, and not with deoxyguanosine derivatives obtained with isomer II (Fig. 2a). Further evidence is provided in Fig. 2b which indicates that after acetylation the radioactive product was clearly separated from the acetylated isomer II adducts.

The deoxyguanosine adduct formed *in vitro* which corresponded to the major DNA adduct formed in human and bovine tissues was then isolated in a quantity sufficient for CD spectra (Fig. 3). The spectrum of this adduct was identical to that previously reported for the major guanosine adduct^{7,8}. This is consistent with the fact that the presence or absence of the 2'-hydroxyl group of the sugar residue should have little or no influence on the CD spectrum. The CD spectrum is extremely complex since it consists of extrema due to the perturbed pyrene and guanine chromophores as well as the spatial interactions between the two chromophores, the latter being predominant. The identity of the CD spectra of the deoxyguanosine and guanosine adducts and the fact that the absolute stereochemistry of the BPDE I must be 7R (refs 15, 17) indicates that, except for the 2'-hydroxyl group, the structures and absolute stereochemistry of the two adducts are identical (see Fig. 3). As in the case of the RNA adduct^{5,7-9}, the 2-amino group of guanine attacks position 10 of the 7R enantiomer of BPDE I through *trans* opening of the epoxide.

Both human and bovine RNA samples displayed minor adducts, the analogues of which were not detected in the DNA samples. The probable origin of two of these is described above, others were present in insufficient amount for identification. Possible explanations for the greater heterogeneity of adducts of RNA include the following. (1) The double stranded property of native DNA may contribute selectivity to its modification. (2) Both BPDE isomers I and II may be formed in the cytoplasm, but due to the greater instability of isomer II (ref. 18) it may react only with cytoplasmic RNA and not reach the nuclear DNA. (3) There

Fig. 2 HPLC profiles of human and bovine DNA adducts formed by bronchial explants incubated with ³H-BP. The radioactive human or bovine DNA which eluted in the void volume of the Sephadex LH 20 column (see Fig. 1 legend) was digested with DNase I, snake and spleen phosphodiesterases and alkaline phosphatase¹². The modified deoxynucleosides were isolated by Sephadex LH 20 chromatography and co-chromatographed on HPLC with ultraviolet markers synthesised *in vitro*. a, Compares the HPLC profile of the human ³H-deoxynucleoside adducts to that of deoxyguanosine adducts synthesised *in vitro* by reaction of 5' dGMP with either BPDE I (dG-I) or BPDE II (dG-II). HPLC conditions: Lichrosorb C18, 5 μ m, 3.2 \times 250 mm column (Rainin), 2,500 pounds per square inch, 45% methanol, 50 $^{\circ}$ C. The major (>90%) *in vivo* DNA adduct eluted with a dG adduct (dGI-3) formed from BPDE I. b, Compares the HPLC profile of the acetates of ³H-bovine deoxynucleoside adducts to those of the acetates of dG-I and dG-II. HPLC conditions: Zorbax ODS, 2.1 \times 250 mm column (Dupont); 2,500 pounds per square inch, linear gradient of 50–65% methanol in 50 min, 50 $^{\circ}$ C. A single radioactive *in vitro* product was obtained (upper panel, b) which, when reanalysed on HPLC with 55% methanol as solvent, was cochromatographic with the acetate of dGI-3. Similar results were obtained with the acetate of the major ³H-human deoxynucleoside adduct.

Fig. 3 *a*, CD and *b*, ultraviolet spectra of dG1-3 (the product corresponding to the major *in vitro* DNA adduct from human and bovine bronchial explants). The sample was prepared and purified by HPLC as described in Fig. 2. Spectra in 50% water-methanol. The CD $\Delta\epsilon$ values are 30% lower than previously reported for guanosine adducts⁷ because of a computational error in the previous data. The ultraviolet spectrum of the adduct is dominated by the strong bands of the pyrene chromophore, the transitions of which are: shoulder (shaded area) at 350–360 nm, L_b , short axis; 310–355 nm, L_a , long axis; 260–290 nm, L_b , short axis²². These interact with the guanine transitions at 260–270 nm, as shown by the solid line in the guanine structure, to give rise to the complex CD spectrum.

may exist a separate nuclear monooxygenase system¹⁹ which has greater stereospecificity than the cytoplasmic system in the synthesis of BPDE. Further studies are required to distinguish these possibilities.

Our investigations on the major BP metabolite responsible for covalent binding to cellular DNA in human tissue, and our evidence for the structure of the DNA adduct which is formed may contribute to the understanding of the possible human hazards associated with environmental exposure to BP and other polycyclic aromatic hydrocarbons.

Nucleotide sequence of *Bombyx mori* L. tRNA₁^{Gly}

THE functional adaptation of the tRNA population in the posterior silk gland of the silkworm *Bombyx mori* L during growth and secretion of fibroin¹ is the result of changes in the predominant isoaccepting tRNA species to accord with the frequency of various codons in fibroin mRNA (refs 2–4). tRNA adaptation to fibroin biosynthesis can be demonstrated by polyacrylamide gel electrophoresis maps. The main glycine codons GGU and GGA of fibroin mRNA (ref. 3) are translated by means of two prevalent iso-tRNA^{Gly} species: iso-tRNA₁^{Gly} decodes GGU and GGC whereas iso-tRNA₂^{Gly} decodes GGA (refs 4–6). The glycine tRNA₁, the first sequenced tRNA from an insect⁶, has 74 nucleotides and relatively few modified residues⁷: one thymidine, one pseudouridine, one dihydrouridine, one 1-methyl adenine, 1-methyl guanosine, four 5-methyl cytidine and one unusual 2'-O-methyl uridine in the acceptor stem. It carries the expected GCC anticodon⁴. Comparison with three other homodecoding tRNA_{GCC}^{Gly} species reveals a high degree of homology.

The functional adaptation of tRNA to the amino acid composition of proteins being synthesised is best demonstrated by studying the quantitative changes of well-defined iso-tRNA species during development of the silk gland of the lepidopteran *Bombyx mori* L., which produces massive amounts of fibroin and sericin in the posterior and middle part respectively^{1,2}. The observed changes in tRNA species during the last larval stage before cocoon spinning are closely associated with the codon frequencies of glycine, alanine and serine in the rapidly accumulating fibroin mRNA, mainly GGU: GGA in a ratio of 1.4:1, GCU and UCA (refs 2–5). The sequence of the prominent tRNA₁^{Gly} species supports our predictions, based on triplet binding, of the presence of a GCC anticodon able to decode GGU and GGC codons^{4,6}. This remarkable iso-tRNA₁^{Gly} represents $20 \pm 3\%$ of total tRNA at the end of the secretion phase of fibroin in the posterior silk gland whereas iso-tRNA₂^{Gly} able to decode GGA and GGG accounts for $15 \pm 2\%$. Their ratio matches that of the corresponding codons in fibroin mRNA (refs 2, 8).

The posterior silk glands from hybrids of European strains 200 and 300 were dissected at the end of the last larval instar. Transfer

RNA was extracted as previously described⁹ and tRNA₁^{Gly} purified by a 1,500 transfer counter-current distribution to 80% and subjected to a final DEAE-cellulose chromatography at 65 °C 7 M urea^{6,7}. This tRNA species is strongly polar, because of a low ratio of adenine to pyrimidine⁷, and has been identified by two-dimensional polyacrylamide gel electrophoresis as shown in Fig. 1. Co-electrophoresis of tRNA₁^{Gly} from the middle silk gland secreting sericin and from the carcass rich in a chitin-associated protein shows that they have identical mobility. The pancreatic and T₁ RNase digestions, separation of the oligonucleotides on neutral and acidic DEAE-cellulose columns and high voltage electrophoresis, nucleotide analysis by thin-layer chromatography and all subsequent steps for further sequence analysis were carried out as described previously¹⁰. The identity of oligonucleotides has been checked again with ³²P-tRNA₁^{Gly} isolated from two-dimensional gel and subjected to a mini-fingerprint⁸: electrophoresis on cellulose acetate strip at pH 3.5 followed by homochromatography on a PEI-cellulose thin-layer plate for the second dimension. A partial digestion with T₁ RNase, which yields mainly two halves, allows us to reconstruct unambiguously a unique sequence.

The complete sequence of *B. mori* tRNA₁^{Gly} or tRNA_{GCC}^{Gly} is shown in Fig. 2 arranged in the cloverleaf model. It belongs to class I of tRNA characterised by four base pairs in the dihydrouridine stem and a short variable loop with four nucleotides. In addition to

Fig. 1 Two-dimensional polyacrylamide gel electrophoresis of posterior silk gland tRNA. One A₂₆₀ unit of total tRNA from the posterior silk gland of *B. mori* 7-day-old larvae is applied to a 9.6% acrylamide gel, 7 M urea, Tris-borate buffer pH 8.2 and run over 35 cm for 45 h at 450 V (first dimension from right to left). The gel strip is cut out and embedded atop 20% acrylamide, 4 M urea prepolymerised gel slab. The electrophoresis is run in the same buffer for 60 h at 120 V (second dimension from top to bottom). tRNA spots are located after staining with 0.2% methylene blue solution in 2% sodium acetate buffer pH 5.0 or by autoradiography using ³²P-labelled tRNA. Identification is performed either by acylation and deamination with nitrous acid to stabilise the ester bond or by using purified samples of tRNA species from counter-current distribution and/or BD-cellulose chromatography^{8,16}.

the standard 23 invariant and semi-variant residues responsible for the maintenance of the tertiary structure of the macromolecule¹¹ shown in the composite diagram of Fig. 3, the tRNA₁^{Gly} reveals some characteristic features already mentioned⁶. The occurrence of a Um in position 4 of the acceptor stem seems to be a property of eukaryotic tRNA_{GCC}^{Gly}, which have been sequenced, since only tRNA₁^{Gly} species from yeast¹² and from wheat germ¹³ carry a 2'-O-methyl cytidine in the homologous position. The minor spot of tRNA₁^{Gly}, (a in Fig. 1), could be the non-methylated form⁸. The guanosine residue in the wobble position of the predicted GCC anticodon enables tRNA₁^{Gly} species to decode the main GGU codon found in fibroin mRNA (ref. 3). Its exposed position makes an easy partial digestion with T₁ RNase yielding two halves (a pGp 5'-terminal fragment of 33 nucleotides and the 3' end of 41 nucleotides with different compositions) useful in reconstructing

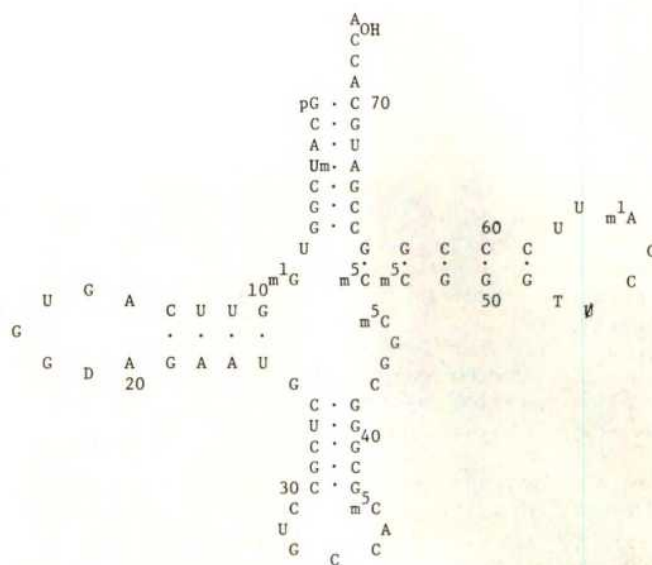

Fig. 2 Nucleotide sequence of *Bombyx mori* L. major tRNA₁^{Gly} or tRNA_{GCC}^{Gly} arranged in the cloverleaf model. Standard abbreviations are used for the nucleotides. Base pairs are represented by a dot. Specific cleavages with pancreatic and T₁ RNases yield 20 and 18 digestion products respectively. Partial T₁ digestion at the exposed guanosine in the wobble position 33 gives two halves used to reconstruct unambiguously the unique sequence. The iso-tRNA₁^{Gly} from posterior silk gland contains the GCC anticodon able to decode the main codon GGU found in fibroin mRNA³.

the total sequence. Like the other tRNA species decoding GNN triplets, the anticodon loop does not contain a hypermodified purine in position 36. The m⁵C residue at position 37 has been found in the homocoding tRNA_{GCC}^{Gly} from wheat germ¹³ as well as in the major cytoplasmic valine tRNA of mouse myeloma cells¹⁴, which carries the homologous tetranucleotide CAm⁵CGp. The m⁵C triplet located at the junction of the short variable loop and the TΨC stem also occurs only in tRNA_{GCC}^{Gly} species of

Fig. 3 Composite diagram of homocoding tRNA_{GCC}^{Gly} species. We have included four tRNA_{Gly} species able to decode GGU and GGC: tRNA₃^{Gly} from *E. coli*¹⁷, tRNA₁^{Gly} from yeast¹², wheat germ¹³ and *B. mori*. Nucleotides not common are indicated by dot. The 23 invariant and semi-variant nucleotides are represented in small letters. R stands for purine and Y for pyrimidine. Those homologous to the four tRNA_{GCC}^{Gly} species are noted in large letters. In parentheses we have shown additional similarities between the three eukaryotic species.

higher eukaryotic organisms from wheat germ to human placenta¹⁵. The presence of four m⁵C residues specific for the preponderant iso-tRNA₁^{Gly}, in contrast to the two found in the iso-tRNA₂^{Gly}, can be used as a marker for tRNA biosynthesis studies^{7,8}. We have to point out the presence of the 'invariant' thymidine in the T Ψ C sequence is not ubiquitous with respect to the *B.mori* tRNA species. Our nucleoside and fingerprint analysis demonstrate clearly that both preponderant tRNA_{2a}^{Ala} species (specific for the posterior silk gland) and tRNA_{2b}^{Ala} (common in all silkworm tissue)¹⁶ have no thymidine^{7,8}.

Figure 3 represents the composite diagram of known homodecoding tRNA_{GCC}^{Gly} species: tRNA₃^{Gly} from *E.coli*¹⁷, tRNA₁^{Gly} from yeast¹², wheat germ¹³ and *B.mori*. Considering both purine residues as R and pyrimidine residues as Y, the homodecoding tRNA_{GCC}^{Gly} species so far sequenced have 71.0% homology whereas eukaryotic species alone have 77.0%. There is an increase in sequence homology from *E.coli* tRNA_{GCC}^{Gly} to yeast, wheat germ and *B.mori* corresponding to their phylogenetic relationship. Because of its great variability, however, the anticodon stem could be considered as a target susceptible to evolutionary pressure. This reinforces the presumption that the central part of the tRNA molecule is involved in the recognition sites of cognate ligase and ribosome.

The structural work has been done in Dr G. Dirheimer's laboratory and supported by a grant from INSERM (no 76.10613) and the Fondation pour la Recherche Médicale Française. We thank Dr Dirheimer for his interest and Ms Ch.Fix for her excellent technical assistance. We are also indebted to Dr J. Daillie for his invaluable encouragement and partial support from the DGRST, Interactions Moléculaires en Biologie.

Melting fine structure of DNA fragments of known base sequence from ϕ X174

THERE is much experimental evidence of discrete unfolding of double-stranded DNA, revealed as fine structures in the melting profile (refs 1–4 and refs therein). Although this is believed to reflect aspects of the nature of the base sequence through the instability of AT and GC base pairs⁵, detailed quantitative analysis is hindered by factors such as the highly cooperative nature of double-helix stabilisation by base stacking and the long-range correlation of helical states through the entropy effect of the unfolded loop. Furthermore, the lack of appropriate nomenclature for the base sequence has complicated discussion. Fortunately, essentially the whole base sequence of the DNA of bacteriophage ϕ X174 has been determined⁶, and we present

Fig. 1 Melting profiles of Y₁-fragment (a) and Y₂-fragment (b) of DNA of phage ϕ X174. Double-stranded, closed-circular replicative form (RFI) of ϕ X174 phage was prepared from ϕ X174 am3-infected *Escherichia coli* HF4704 cells as before⁷. The RFI molecules were cleaved by restriction enzyme *Hap*II, and the products were separated by polyacrylamide gel electrophoresis⁸. The gels were scanned at 260 nm using a Gilford spectrophotometer 250 to define the regions of the DNA fragments. The gel regions containing the largest (Y₁) and the second largest (Y₂) fragments were excised and these fragments were extracted as in ref. 9. Melting profiles were obtained with a minicomputer-controlled on-line melting plotter¹. The displays are made in differential form as d(1- θ)/dT against T, where θ is the helix content obtained by the optical density measurement at 260 nm, and T is the temperature. The ordinate is not normalised to the fragment length. Two results of independent measurements are shown by the solid and dotted lines in each figure.

here melting profiles of two fragments obtained from the replicative form by means of the restriction enzyme *Hap*II, and examine them with reference to their base sequence.

The differentiated melting profiles of fragments Y₁ (2,745 base pairs: position 3360–5375–729) and Y₂ (1,690 base pairs: position 1104–2793) measured in a 0.1 M SSC aqueous solution are shown in Fig. 1a and b, which have three and two well separated peaks, respectively, with some reproducible hyperfine structure in several of the peaks. Numerical data for the characteristics of the peaks are listed in Table 1.

The base sequences of these fragments are also shown in Fig. 2a and b in the form of the distribution function $P_n(x)$ of the G+C content, x, of sections each containing n base pairs along the DNA fragment, the first section starting with the first base pair, the second with the second base pair and so on until the whole fragment is covered. If the base sequence of the fragment is purely random and sufficiently long compared with the length of the section, n, the distribution function should agree with the binomial distribution

$$P_n(x) = \frac{n!}{\{n(1-x)\}!\{nx\}!} X_0^{nx}(1-X_0)^{n(1-x)}$$

where X_0 is the G+C content of the whole fragment. The binomial distribution for a small value of n is also plotted in the same figure for comparison.

We have speculated that a peak in the melting profile corresponds to a homostability region or regions with a fairly homogeneous base sequence, because computer simulations based on the established molecular thermodynamic parameters for several randomly generated base sequences did not reproduce sharp peaks as obtained in melting experiments^{1,4}. On the other hand, Lyubchenko *et al.* have shown that a sharp fine structure can be simulated by some computer-generated random base sequences³. But, arguments based on a limited number of such sequences may not be meaningful, because a DNA molecule of 1,000 base pairs, for example, has $2^{1,000}$ varieties of base sequence.

We therefore draw the following conclusions. (1) Fragments

Fig. 2 Local segmental distribution of G+C content in Y_1 -fragment (a) and Y_2 -fragment (b) of DNA of phage $\Phi X174$. The distribution function is expressed in terms of the G+C content, x , of sections each containing n base pairs along the DNA fragment, the first section starting with the first base pair, the second with the second base pair and so on until the whole fragment is covered. The last section, therefore starts with $(N-n+1)$ th pair where N is the total number of base pairs in the fragment. Two distributions with $n=19$ and $n=499$ are shown. The binomial distribution for $n=19$ is shown by crosses.

Table 1 Numerical data for the melting peaks

Fragment	Peak no.	$T_m(^{\circ}\text{C})$	$2\sigma^{\dagger}$	Length (base pairs)
Y_1	1 \ddagger	70.8 ± 0.1	0.54	1,570
	2 \ddagger	72.3 ± 0.1	0.53	850
	3	73.4 ± 0.1	0.42	330
Y_2^*	1	70.6 ± 0.1	0.39	680
	2 \ddagger	71.8 ± 0.1	0.56	1,010

Peaks were measured in 0.1 ssc.

* Mean value of two measurements.

\dagger Full width at $0.61 \times$ maximum height.

\ddagger Peak having hyperfine structure.

Y_1 and Y_2 of $\Phi X174$ DNA have well resolved fine structures corresponding to the cooperative melting of sections containing 300–1,500 base pairs (Fig. 1). (2) The base sequences of these fragments are fairly random when observed in short lengths, 'random' being defined in terms of several criteria, such as the nearest neighbour base frequency, autocorrelation of the base sequence and the binomial distribution of the G+C content (Fig. 2). (3) The distribution of the local segmental G+C content shows some deviation from a smooth distribution when it is averaged over several hundred bases (Fig. 2). Whether this distribution is statistical or has some functional significance cannot be determined because of the small number of samples available. (4) The melting profiles seem to reflect the long-range base distributions when Figs 1 and 2 are compared. (5) Detailed analysis shows that cooperativity in the melting of DNA is much stronger than previously expected, and the value of the cooperativity parameter used by Lyubchenko *et al.*³ seems to be more appropriate than that used earlier.

It is important that ambiguous and unrealistic terminology, such as 'homogeneous' or 'random', should not be used to describe the nature of base sequences with limited length. Instead, because the melting profile of a known sequence unambiguously shows several peaks, we are working on the determination of the molecular thermodynamic parameters for the melting of DNA. A quantitative discussion on the relation between the base sequence and the melting profile will be published elsewhere.

We thank Professor M. Takanami for restriction endonuclease.

matters arising

Generation length and rates of hominoid molecular evolution

BENVENISTE and Todaro¹ recently presented a large and valuable body of DNA annealing data bearing on Old World monkey, ape, and human evolutionary relationships. For an evolutionary biologist, the basic advantages of such data lie in their potential to provide phylogenetic information with minimal reference to other sources of comparative data on the organisms under study. That is, the molecular data set can, in large part, be tested internally and thus tell its own message. We therefore find it disturbing that Benveniste and Todaro have carried out a phylogenetic interpretation of their data using the assumption that generation length affects rates of nucleic acid evolution—especially when one notes that they present on the same page data from their own work which strongly suggest that it does not. We have specific reference to Fig. 1 and Table 2 of ref. 1.

In Fig. 1 of ref. 1 the authors calculate intrahominoid divergence times assuming an Old World monkey-ape time of 30 Myr and a rate of DNA base substitution inversely proportional to the estimated generation lengths involved. That is, longer generation length forms would undergo less rapid DNA evolutionary change. In this fashion, dates reasonably compatible with current palaeontological views of hominoid evolution² are obtained. Thus Benveniste and Todaro fail to note that the data of their Tables 1 and 2 show no such dependence on the proposed generation lengths.

We can reach this conclusion because the generation length hypothesis is, fortunately, subject to direct test. Whatever the divergence time of, for example, the human and gibbon lineages, both have obviously existed for the same length of time since their separation. If the generation length hypothesis were valid, then the human line would have accumulated fewer nucleotide substitutions in that time than the gibbon line. Therefore our DNA would today remain more similar to that of a monkey than is modern gibbon DNA. Specifically we note the human-gibbon $\Delta T_m R$ of 6.9 °C. In the legend to Fig. 1, Benveniste and Todaro state that they assume for the gibbon line a value of 1 °C $\Delta T_m R$ per 3 Myr of evolution, and for the human line 1 °C $\Delta T_m R$ per 5 Myr. Since the

Table 1 Intraprimate relative molecular distances

Taxa compared	DNA*†	Albumin plus* Transferrin Immunology	Time of divergence (Myr)
<i>Homo-Pan-Gorilla</i>	0.14	0.12	4-5
(H,P,G)- <i>Pongo</i>	0.3	0.25	9-11
(H,P,G)- <i>Hylobates</i>	0.36	0.29	11-13
Apes, man-Old World monkeys	0.60	0.57	20-22
Catarrhini-Platyrrhini	1.0	1.0	35-38
Prosimii-Anthropoidea	—‡	2.0	70-75

*Each number in these columns is the ratio of the distance between those taxa and the catarrhini-platyrrhini distance.

†The first three numbers are means of the relevant data points in refs. 1, 3, and 9.

‡Prosimian-anthropoid differences are apparently too large to give reliable DNA data. But, our immunological studies of albumin and transferrin evolution in primates and other mammals show very similar amounts of change along the various primate lineages along with a prosimian-anthropoid distance almost exactly twice that between New and Old World higher primates (platyrrhines and catarrhines)¹⁰. Placing the beginnings of the adaptive radiation leading to modern primates at 70-75 Myr, this gives a platyrrhini-catarrhini separation at ~ 35 Myr (ref. 11).

human and gibbon lines separated, then, the latter would have accumulated 5/3 as many nucleotide substitutions. That is, of the 6.9 °C, 4.3 °C would have accumulated along the gibbon line, and 2.6 °C along the human. Thus when human and gibbon DNAs were compared to that of an Old World monkey (baboon), that of the gibbon should have given a $\Delta T_m R$ 1.7 °C larger than that given by human DNA, and such a difference is several times greater than the experimental errors implicit in such DNA comparisons. Yet precisely this comparison is presented in Tables 1 and 2 of ref. 1, where we note the baboon-human difference to be 9.1 °C, while the baboon-gibbon difference is 9.05 °C. Indeed, all five hominoids tested are in the range 9.15 ± 0.15 °C, that is identical within experimental error. As the actual data, by direct test, fail to show the assumed generation length effect, why allege its influence in time of divergence calculations? This is, after all, not a new issue. Other authors have argued for generation length effects in hominoid molecular evolution^{3,4}, and had their arguments answered⁵⁻⁸. Indeed, Kohne³, though favouring the generation length hypothesis, had nevertheless allocated the same amounts of change along the human and gibbon DNA lineages as long ago as 1970.

In the absence of any documentation of a generation length effect, and with the direct demonstration that amounts of DNA change along the various primate lineages are a function of the temporal lengths of those lineages, we feel amply justified in using the available data to calculate divergence times as in the accompanying Table 1.

The particular virtue of protein and

nucleic acid data is that we can actually count interspecies differences in constant units and allocate them along lineages with minimal dependence on non-molecular evidence. Unfortunately, it has far too often been the case that the molecular data have been forced into a misguided congruence with what is thought to be hard evidence from a sparse and spotty primate fossil record—thereby long-delaying the day when those data will achieve their proper and invaluable place in providing that framework within which to most usefully view other bodies of evolutionary evidence, including those deriving from the fossil record.

TODARO AND BENVENISTE REPLY—We are aware of the long-standing discussion in the literature concerning the effect of generation length of a species on the rate of accumulation of base-pair mutations

in cellular DNA (refs 1, 2) and amino acid substitutions in proteins^{3,4}. But, the main conclusions of our paper did not depend on knowing the proper corrections to apply, if any, for the lengthened generation times in the higher apes and man as compared to the Old World monkeys. The conclusions were that (1), nucleic acid sequences related to the genome of the genetically transmitted baboon type C virus can be detected in the cellular DNA of all Old World monkeys and apes; (2), the baboon type C virus specific sequences can be used to discriminate between those Old World monkeys and apes whose habitat is Africa (baboon, mangabey, African green monkey, colobus, chimpanzee, gorilla) and those whose habitat is Asia (various macaques, langurs, gibbon, orangutan); (3), the data obtained with human DNA closely fit the pattern observed with the Asian apes. The suggestion was therefore made that most of man's evolution since his divergence from the other apes had occurred in Asia rather than in Africa.

Sarich and Cronin point out that the hypothesis that animals with longer generation times accumulate fewer mutations per unit of chronological time as suggested by Kohne¹, Lovejoy⁵, and others is subject to a direct test. The accumulation of nucleotide substitutions along the gibbon lineage, where the generation length has changed less, compared to Old World monkeys, should be more than it is along the human lineage where the time of sexual maturity and the maximum lifetime potential⁶ have markedly increased. Although we agree with him that this is experimentally testable, the differences would be small. If man had a common ancestor with the chimpanzee and gorilla as recently as 4 Myr ago as Sarich has proposed^{7,8}, then the effect of the recent prolonged generation time of ancestral man would be even more difficult to detect. We would not conclude that the cellular DNA data as reported in the manuscript was performed in a sufficiently rigorous fashion to 'prove' the lack of effect of a generation time. In our initial studies we did not see a difference along the two lineages, but more refined studies directed specifically at that question might reveal small differences; such a study is currently in progress.

Our data concerning the relationships among the cellular DNA of Old World monkeys and apes agree quite well with the extensive immunological studies of Sarich, Cronin, and others. For example, we state that 'the extent of nucleic acid sequence divergence among chimpanzee, gorilla, and man is three to four times less than that between any of these three Homininae and the Old World monkeys'. But, there is also a considerable body of palaeontological evidence suggesting that apes and hominids had differentiated long before the time Sarich and associates

place the chimp-gorilla-man common ancestor^{6,9}. With methods for dating fossils improving, this is now a substantial body of data we felt should not be ignored. It will be intriguing to see if the traditional palaeontological approach can be correlated to the data being obtained with respect to protein and nucleic acid evolution, or whether the discrepancy in the two methodologies is as large as Sarich suggests.

Complementation of immune response genes for (T,G)-A-L

Two years ago we reported the results of experiments which demonstrated the *in vivo* complementation of immune response genes required for a response to (T,G)-A-L (ref. 1). Subsequent experiments seemed to confirm and extend this result². Unfortunately others have been unable to repeat our results in as much as they find no evidence for complementation in the response to (T,G)-A-L (ref. 3). Recently in attempts to repeat our original findings with (B10.M×B10.Br)F₁ we also have been unable to do so but now find responses to (T,G)-A-L similar to those reported by others³. We wish, therefore, to express our reservations concerning complementation in the (B10.M×B10.Br)F₁ in the hope that further study of this phenomenon by ourselves and others will clarify the conditions in which genetic complementation in the response to (T,G)-A-L can occur.

High explosive analogue of the Tunguska Event

JONES¹, observes the existence of an important, but little known experiment. The numerical conclusions however are incorrect, using only the

data cited in the letter. Using the ratio 35,000 to 130 as the diameters of symmetric explosion phenomena for the Tunguska event and the 1966 experiment cited by Jones, respectively, and the relevant scaling law, the corresponding equivalent explosive source strength for the Tunguska event would appear to be of the order of $50 \times (35,000/130)^3$, or about 10^9 t, not the 10^3 t cited. Without accurately computing all the necessary corrections for energy partitioning, actual hydrodynamics, etc., this would provide an estimate of source strength about two orders of magnitude higher than ref. 3 cited therein concludes.

B. W. AUGENSTEIN

- ¹ Jones, G. H. S. *Nature* 267, 605 (1977).

JONES replies: Augenstein is correct, and the calculated values should have read 10^5 kt TNT and 200 Mt nuclear equivalent, these being minimum estimates. The Tunguska event devastated an area 35 km in diameter! It is commented, however, that the very low height of burst, almost a surface burst at this yield, should be retained despite the absence of a crater at Tunguska. I have discussed elsewhere (Suffield Reports 217 and 281), experimental evidence that high yield but low energy density explosions on the surface do not cause craters but do produce airblast and surface seismic effects similar to those from high density explosions. Forest blowdown, for example, is insensitive to the initial energy density but depends upon the total energy release. The lack of a crater at Tunguska is thus evidence of the low density, presumably cometary nature of the bolide.

β -Globin mRNA in Ferrara β^0 -thalassaemia

In their paper on the presence of β -mRNA in Ferrara type β^0 -thalassaemia, Ottolenghi *et al.*¹ stated that our laboratory had obtained "similar findings" to their's with material from one of their patients. Because of possible misinterpretations of that very general statement, we present here the limited data which we did obtain using Ferrara material.

Professor Conconi kindly provided us with ribosomes from one of his patients so that we could attempt to

Fig. 1 Hybridisation of Ferrara β^0 -thalassaemia RNA to human α - and β -cDNA. ●, α -DNA; Δ , β -cDNA.

demonstrate β -globin mRNA, in RNA extracted from these ribosomes, by fingerprint analysis of ^{32}P -labelled cRNA synthesised from cDNA²; cDNA was obtained but the cRNA synthesis failed. We did, however, use a small amount of the starting RNA to assay its relative content of α and β mRNA by molecular hybridisation to human α and β globin cDNA as previously described³. A small amount of β or β -like mRNA was detected (Fig. 1). Unfortunately there was insufficient RNA available to obtain a plateau of hybridisation with β -cDNA but the slope of the β -cDNA hybridisation curve predicts a β -mRNA content in the sample of approximately 4% relative to that of the α mRNA in the same sample. Because we lacked sufficient material to demonstrate a plateau or saturation of hybridisation of Ferrara β -like mRNA with β -cDNA, our results do not help to resolve the discrepancy between the results of Ottolenghi *et al.*¹ and those of Ramirez *et al.*⁴. The latter found that the Ferrara β -like mRNA hybridised incompletely with β cDNA (in contrast to complete hybridisation claimed by Ottolenghi *et al.*) and suggested the presence of a substantial abnormality in the structure of Ferrara β mRNA.

Our hybridisation results with Ferrara thalassaemia mRNA are similar to those which we have obtained⁵ with total reticulocyte RNA from a variety of β^0 -thalassaemic patients of different ethnic backgrounds (Southern Italian, Greek, Algerian, Asian and Chinese). In some of these patients there is less than 1% as much β -like mRNA as α mRNA⁶ and this could be due to cross hybridisation of δ -chain mRNA of HbA₂ to β cDNA. In approximately half the patients, however⁵, we have found 4–15% as much β -like mRNA as α mRNA; the latter value is probably too high to be accounted for by δ -chain mRNA alone. Other workers have found substantially more β -like mRNA

in non-Ferrara β^0 thalassaemic reticulocytes^{4,7}. We were unable to identify, by fingerprint analysis of ^{125}I -labelled mRNA, β -chain specific oligonucleotides in RNA from two of our patients with low levels of β -like mRNA detected by hybridisation⁵. But, Temple *et al.*⁸ have been successful in detecting β -chain specific mRNA sequences in one of their patients with β^0 -thalassaemia.

We suggest that until specific structural differences in the β -globin gene of β^0 -thalassaemics are detected by gene mapping or nucleotide sequence studies, one cannot make any definitive conclusions as to the precise molecular basis of the varied forms of β^0 -thalassaemia. The β -globin genes seem to be present in all cases of β^0 -thalassaemia in which they have been sought (refs 4, 7–9 and Tuan, D.G.H. and B.G.F., unpublished). The different results obtained by hybridisation assays of globin mRNA need to be related to specific structural defects in the β -globin gene DNA before one can feel confident about classifying the β^0 -thalassaemias found in different populations into specific molecular subtypes.

OTTOLENGHI ET AL. REPLY—Forget and Hillman conclude that the different results obtained by hybridisation assay of globin mRNA by various groups^{1–5} do not yet allow the classification of β^0 -thalassaemia found in different populations into specific molecular subtypes; this conclusion is based on the wide range of values reported for β -globin-like RNA in non-Ferrara β^0 -thalassaemic patients, and the overlapping of some of these values with those determined by ourselves⁵ and by Forget and Hillman in Ferrara β^0 -patients. As has been pointed out by Benz^{6,7}, however, discrepancies in the level of β -like sequences found in β^0 -thalassaemias may arise as the result of technical differences between laboratories.

In our laboratory we have compared

several different groups of patients. β -like mRNA has been either undetectable in non-Ferrara β^0 -thalassaemic reticulocytes⁸ or present at levels of less than 1% relative to α -sequences (a value that is compatible with cross-hybridisation between cDNA _{β} and mRNA _{δ} sequences), whereas in reticulocytes of Ferrara β^0 -thalassaemics levels of up to 8% can be detected. Moreover, when sufficient RNA has been available, the T_m of the hybrid formed between the low amounts of ' β -like RNA' from non-Ferrara β^0 -thalassaemics (? δ -mRNA) and cDNA _{β} has been 7–8 °C lower than that found for true β -mRNA–cDNA hybrids⁸, again in significant contrast with what we find in Ferrara thalassaemia.

We, therefore, conclude that our results (refs 5, 9 and unpublished) taken together with the translational data of Conconi's group^{10,11} allow us to divide β^0 -thalassaemia into at least two different types, a β -mRNA negative type and a β -mRNA positive type; whether other forms of β^0 -thalassaemia in which significant levels of β -mRNA have been demonstrated have any relationship with the Ferrara type of thalassaemia remains to be investigated, and we agree will require translational experiments, as well as gene mapping and nucleotide sequence studies.

reviews

Introducing relativity

Paul Davies

Essential Relativity: Special, General and Cosmological. Second edition. By W. Rindler. Pp. xv+284. (Springer: New York and Berlin, 1977.) DM67.70; \$29.80.

AFTER eight years I still find Rindler's book one of the best introductions to the theory of relativity, and I was eager to read his second edition. The title *Essential Relativity* is an apt one, for even though this edition contains some new material, only the bare essentials of the subject are discussed. This is not a drawback, because Rindler manages somehow to get very far with very little investment in detailed calculation or protracted conceptual deliberation. In this respect it makes ideal introductory reading for students of physics, although mathematics students will not find much in the way of modern differential geometry or topology.

In the preface to the second edition the author explains how the emphasis of the book is on the conceptual foundations rather than the mathematical development of relativity theory. Proofs are kept to a minimum and many examples and mathematically-oriented discussion are only punctuated by, rather than rooted in, hard equations. Nevertheless, the reader is taken swiftly and effortlessly (maybe somewhat deceptively) through pre-Einstein ideas of space and time, basic special relativity, Minkowski space and four-vectors, tensors, particle mechanics and electrodynamics. Then we move into general relativity, which starts out with the most 'conceptual' section of the book, in which the idea of curved space-time is explained in just a few pages. The Schwarzschild metric just seems to pop out from this discussion, to be followed by an updated description of black holes and the Kuskal manifold.

When I re-read the section on uniformly accelerated observers in Minkowski space, I was disappointed to find that the author, whose name is famous for his connection with the co-ordination of Minkowski space based on a collection of accelerating observers, had not chosen to expand more on this very useful construction. I have found the ideas of uniform acceleration both useful and elegant exercises for undergraduates, as well as

a very profitable analogy for the more advanced discussions of black holes.

The book concludes with a section on cosmology, and once again I was interested to see if Rindler's discussion of horizons had been elaborated. The earlier edition was one of the first undergraduate textbooks of its time to try and present this subject conceptually. The new edition contains the familiar remarks about crawling bugs and rubber sheets, as well as the usual mathematical conditions for horizons, but also includes some new material and diagrams to help untangle some of the apparent paradoxes associated with them.

Although the organisation of the material is largely the same as before, many sections have been re-written, in the same lucid style. New sections on the plane gravitational wave and linearised general relativity, as well as two appendices on curvature and Maxwell theory, have been added. I was disappointed at the price for a book which should be aiming at the 'mass' student market, to which it is admirably suited. How many undergraduates will pay nearly £20 for a basic course textbook? □

Paul Davies is Lecturer in Mathematics at King's College, University of London, UK.

Immunological series

Comprehensive Immunology. Vol. 1: Immunology and Aging. Edited by T. Makinodan and E. Yunis. Pp. 208. Vol. 2: Biological Amplification Systems in Immunology. Edited by N. K. Day and R. A. Good. Pp. 325. (Plenum: New York and London, 1977.) \$27 each volume.

THE new series *Comprehensive Immunology* is intended eventually to cover all aspects of immunology with "definitive analyses, thoughtful reviews and probing discussions". There already exist several good series on immunological subjects and the launching of another cannot be greeted with un-mixed joy. These first two volumes, however, are well produced and have some valuable features. If their standard can be maintained, the series should prove useful.

The appearance of *Immunology and Aging* is timely, since no comprehensive review has been available and increasing interest is being shown in the field. It is also a good moment to look back over the large amount of data that have accumulated on ageing in relation to the immune system. We are still far from understanding this relationship, and it is certainly complex. The thymus and T lymphocytes, however, are widely believed to be among the central characters in the drama, and several papers emphasise this from various points of view. The known intricacies of the membrane structure and physiological functions of T lymphocytes have

been multiplying so rapidly of late that T-dependent interpretations of gerontological phenomena tend to age rather quickly; but this problem should be resolved within the next few years. Among other good chapters are two dealing with germ-free mice and congenitally athymic (nude) mice and their value in the study of ageing. Overall, the volume can be recommended to anyone seeking an introduction to both biological and clinical aspects of the subject, and the extensive reference lists make it an excellent source book.

I tried the title *Biological Amplification Systems in Immunology* on several immunological colleagues, inviting speculation on the contents of this volume. They produced a range of suggestions, none of which approximated to the truth. I can now reveal exclusively to readers of *Nature* that the book is about complement. Probably an expert on complement would have tumbled to it instantly, but then I don't think that the book is really intended for him. The 15 chapters cover the multiple roles of the complement system, as well as its biosynthesis, phylogeny, ontogeny and genetics. There are also discussions of leukocyte chemotaxis and of pathways activated by Hageman Factor. It seems a pity that this useful collection of reviews should be hidden under such an enigmatic title.

H. S. Micklem

H. S. Micklem is Reader in Zoology at the University of Edinburgh, UK.

Unparalleled textbook of plant anatomy

Anatomy of Seed Plants. Second edition. Pp. 550. By Katherine Esau. (Wiley: London and New York, 1977.) \$21.25; £11.50.

TWENTY FOUR YEARS AGO, Professor Katherine Esau published her first book, *Plant Anatomy*. This book rapidly established itself as a standard by which all others have subsequently been judged. As Professor Esau herself points out, however, there was also a need for a shorter book for students who have relatively limited experience in the study of plants. For that reason *Anatomy of Seed Plants* was first published in 1960 and is now seen in its second edition.

Anatomy of Seed Plants still has to be viewed against the broader, and deeper, backcloth set by *Plant Anatomy* itself, but it remains an attractive, informative and authoritative book in its own right, even if its price will restrict ownership more severely than one might hope. An important feature of this second edition is that it incorporates very significant changes and is very much more than a new edition in name alone.

An immediately apparent change is in the page format which is now enlarged to 23.3 cm × 18.9 cm from the previous 22.8 cm × 14.9 cm—a 30% increase in area. This, together with the fact that the book is extended from 376 to 550 pages, has allowed incorporation of much new material, although the larger page size has often been wasted where micrographs and diagrams from the first edition have been reproduced at the same size. The pleasant format, together with two-column presentation, a clearly legible type-face and a balanced distribution of text and illustrations, has led to the production of a book that demands to be read.

Having attracted the reader's attention, what is to be found inside? A major, and immediately obvious feature is the inclusion of numerous electron micrographs. There were only a couple in the first edition, but the present book is liberally laced with them and they are, as are most of the other illustrations chosen, of good quality. If anything, the half-tones in the present volume are of better contrast than those in the original.

Professor Esau's attention to detail is prodigious and only the closest scrutiny of the book reveals many of the smaller changes that have been

made to take account of advances in knowledge or interpretation over the past 16 years. (The abbreviation for micrometre is now given in its proper form (μm) but it is a pity that the Ångström lingers on.) The enormous task of encompassing new information without completely losing sight of the old has largely been achieved by combining subject matter as much as possible, and by referring only to key items of interest within a particular area of study. Similarly, the references, though strictly limited, serve to acquaint the reader with the most recent work and generally include at least one paper from each main laboratory contributing to a specific field of interest. In this way, *Anatomy of Seed Plants* is able to cover a large subject area while allowing the reader

the opportunity to find his way more deeply into plant anatomy if he so desires.

Anatomy of Seed Plants is unashamedly a textbook of anatomy. As such it is unparalleled. Although the modern trend is, and must be, to combine structure and function in our approach to the way plants work, this can only be accomplished if our basic knowledge of plant anatomy is both broad and sound. Professor Esau has ensured that no botanist—whether student or research worker—will have the excuse that the right information is not readily, and attractively, to hand.

A. W. Robards

A. W. Robards is Senior Lecturer in the Department of Biology at the University of York, UK.

Diatom biology

Biology of Diatoms. Edited by Dietrich Werner. Pp. 498. (Blackwell Scientific: Oxford, 1977.) £17.

FEW algal groups have seen such an expansion of interest over the past two decades as the diatoms, and this volume admirably covers the recent developments. It may come as a surprise to many to read on the first page that it is estimated that diatoms contribute 20–25% of the world's net primary production—a figure derived from experimental studies which almost certainly underestimate true production. Such production at the base of so many food chains ought to stimulate work on grazing, yet this is hardly begun and is mentioned on only a few pages.

Although the title might imply that this book can be read to obtain an overall survey of the diatoms, this is not so, and a student with little knowledge of the group would find it difficult. There is no section on morphology, no simple explanation of cell division, few illustrations of the major groups; and those given are of centric genera leaving a student to guess at pennate morphology.

Growth, nutrition, chemical composition, movement, sexuality, ecology are all discussed; in these chapters, each written by a different author, there is a wealth of data and excellent references. The authors of the chapter on the ecology of marine planktonic diatoms have assembled a mass of fascinating data on distribution in the seas of the world which is a valuable contribution to the much neglected topic of biogeography.

In many places, however, the text is clearly written in review form and

many statements merely stimulate and necessitate consultation of the original papers. The chapter on sexuality will be of great value to many students since much of the excellent original work is very discursive and written in German.

A chapter on ultrastructure reviews the literature but is very poorly illustrated with three very indistinct pictures, all of *Cylindrotheca* which has an unusual morphology. This is a pity since there are now several excellent studies of diatom ultrastructure. Also, apart from a few photographs of centric diatoms, the considerable body of information on the ultrastructure of the siliceous components has not been utilised. The old concept of diatoms as a class of the Chrysophyta again crops up in some chapters although they were clearly recognised as a division, Bacillariophyta, in the system of Husted (1930) and are so distinctive that there can be surely little argument about this in 1977.

Biochemical and physiological studies have blossomed in the past two decades, and the information in the chapters on growth, silicate metabolism, photosynthesis, heterotrophic nutrition and biochemical composition will surprise many who have not followed the field closely. The chapter on silicate metabolism is of great value, since it is a synthesis of chemical and biological studies and provides a valuable introduction to the complexities of silicon chemistry.

The combination of authors has resulted in some repetition of data in several chapters but not in any serious way. The book is well produced, relatively free of errors and will be a source of considerable value for many years to come.

Physiological behaviour of cells

Analytical Physiology of Cells and Developing Organisms. By B. C. Goodwin. Pp. 249. (Academic: London and New York, 1977.) £8.50; \$18.50.

THE aim of this book is to present a picture of the physiological behaviour of cells in terms of molecular biology and mathematical models. As the author acknowledges, the choice of material is not comprehensive and reflects his own interests and prejudices. In the first three chapters, Goodwin examines aspects of the behaviour of individual cells. The metabolic network, the adaptation time of which is of the order of seconds, is considered in terms of allosteric enzymes and end-product inhibition. This network is contrasted with the epigenetic one with longer adaptation times (minutes to hours) and in which gene activation and protein synthesis are now major elements. The occurrence of feedback loops in both kinds of systems can lead to complex dynamics such as oscillations. Analogies with statistical thermodynamics are drawn; and this rather formal analysis is extended to the cell cycle.

In considering the various internal networks involved, the important point is made that there may be no single reaction controlling the entry of a cell into the cell cycle: emphasis should be placed instead on a mixture of probabilistic and deterministic processes. The treatment of the cell cycle is, however, unsatisfactory since it provides an inadequate review of current ideas and experiments. For example, although mechanisms based on chalones which are inhibitory are considered, there is little reference to molecules exerting a positive control, for which there is increasing evidence. A nice chapter on biological clocks follows, with an explanation of Winfree's ingenious approach to the eclosion clocks in *Drosophila*. Here, mathematical analysis leads to experiments that could not really be conceived of without that analysis. Unfortunately, most of the other analyses in the book do not seem to have a similar experimental spin-off.

Pattern formation and its relation to gradients and positional information is given quite detailed attention. Emphasis is placed on periodic processes and a membrane wave model is put forward. A formal model to account for the properties of the polar coordinate model of French, Bryant and Bryant is proposed. Goodwin believes in the next

few years we will see the emergence of new dynamical models in which waves and periodicities will feature very strongly. He recognises that gradient-type models of positional information shift the major problem of pattern formation into the area of how the gradients are interpreted by the cells in terms of gene activity, but gives this central theoretical problem inadequate attention.

In the final chapter, he treats the organism as a cognitive and cooperative system. He treats the cell as if it had knowledge about the world which is contained in its control circuits. He also wishes to regard sharp transitions of state at different levels of organisation as being basically similar and analogous to phase transitions.

Goodwin is always worth reading for his independence and insights, but overall this book is disappointing. The mathematics seems to add rather little and too seldom leads to experiments. The approach is not didactic or comprehensive. For theoreticians, however, it is essential.

Lewis Wolpert

Lewis Wolpert is Professor of Biology as Applied to Medicine at the Middlesex Hospital Medical School, London, UK.

Quantum theory

Qualitative Methods in Quantum Theory. By A. B. Migdal. Pp. 435. (W. A. Benjamin: Reading, Massachusetts and London, 1977.) \$21.50.

"THE solution of most problems in theoretical physics begins with the application of the *qualitative methods* which constitute the most attractive and beautiful characteristic of this discipline. By 'qualitative methods' we mean dimensional estimates and estimates made by using simple models, the investigation of limiting cases where one can exploit the smallness of some parameter, the use of the analytic properties of physical quantities, and finally the derivation of consequences from the symmetry properties, that is, the invariance relative to various transformations (eg Lorentz or isotopic invariance). However, as experience in the classroom shows, it is just these aspects of theoretical physics which are most difficult for the beginner." So Academician Migdal introduces the new edition of his book, the first three chapters of which were published in much the same form as

in *Approximation Methods in Quantum Mechanics* (Izdatelstvo Nauka, 1966; English translation, W. A. Benjamin, 1969).

Migdal is a leading exponent of the Landau school of theoretical physics, the members of which have been brought up to know all nine volumes of Landau and Lifshitz. So in this book we have examples from a wide range of subjects. The first chapter covers mainly models in atomic physics. Chapter two is on perturbation theory, and chapter three is on the WKB method and the quasi-classical approximation, a subject which is not normally given much space in textbooks. Chapter four is on analyticity and dispersion relations. Chapter five is on quasi-particle methods in the many-body problem, with applications to quantum fluids and nuclear matter. Chapter six gives a qualitative physical treatment of renormalisation, and a discussion of the Gell-Mann-Low equation and asymptotic freedom.

This book should be required reading for any serious graduate student in theoretical physics.

Renaissance in laser spectroscopy

Frontiers in Laser Spectroscopy. (Les Houches 1975 Session XXVII) Vol. 1. Pp. 472. Vol. 2. Pp. 473–907. Edited by Roger Balian, Serge Haroche and Sylvain Liberman. (North-Holland: Amsterdam, New York and Oxford, 1977.) Dfl. 280; \$114.50.

THESE two volumes present the proceedings of the Les Houches Theoretical Physics Summer School held in July 1975 on the use of lasers in atomic and molecular spectroscopy. The stated aim of the school was to "give a general presentation of the theoretical background necessary to understand light-matter interaction problems, and to present a review of the various new methods in which lasers are now being used to improve our knowledge about atoms, molecules and even about nuclei." Underlying these new methods are the recent exploitation of tunability, of saturation and of coherent transients which have contributed so much of late to the renaissance in spectroscopy. The level of presentation of the proceedings tends to assume previous knowledge at about first-year graduate student level of quantum optics and quantum electronics, and the scope of the discussion is very wide with most of the actively-pursued topics in the field at least mentioned.

Cohen-Tannoudji presents a marginally telegraphic overview of the basic phenomena involved in the interaction of atoms with strong resonant fields, and his thoughtful lectures contain many insights into fundamental problems involving the non-linear saturation of fluorescent emission. This is followed in Volume 1 by lectures on laser theory (Sargent); transient and steady-state response of two- and three-level systems, including a very useful discussion of the semiclassical theory of superradiance (Feld); the theory and observation by stark-switching of optical nutation, free-induction decay, photon echoes and two-photon transitions (Brewer); and single-atom and co-operative quantum beats (Stenholm). These lectures form a coherent and well-presented review of a physically well-defined area.

In Volume 2, this coherence is lost to a certain extent by an attempt to cover a very wide range of techniques and specific applications. The use of lasers in very high resolution spectroscopy of molecules is discussed by Lehmann, Oka, Kelley and Javan. Letokhov discusses the coupling be-

tween electronic and nuclear degrees of freedom in laser-driven transitions and the so-far purely theoretical subject of "laser-nuclear spectroscopy."

Finally, one of the topics which ensures adequate funding, namely isotope separation, is admirably discussed by Letokhov. Also included in these volumes are short seminars by Series, Walther, Cagnac, Haroche, Liberman, Toschek, Mukamel and Monchalin, which are useful as illustrations of particular research problems, although a few should have been (and some have been) published in the primary literature.

Some of these lectures are rather experimental in tone; these though no less valuable, do not quite fit the label of "Ecole d'Été de Physique Théorique." Indeed, an interesting feature

of this field is the ability of the best practitioners (some of them contributing to these volumes) to cross the experimental-theoretical divide to the great benefit of both sides. Since there were only 42 "pupils" attending the school, one would hope that the publication of the proceedings would give a wider circulation to these valuable lectures. The price of these volumes seems designed to ensure that this will not be so. I doubt the value of such lavish publication of conference and Summer school proceedings in hard-back textbook format, with its concomitant delay and inflated cost.

Explosion in myelin research

Myelin. Edited by P. Morell. Pp. xxii+531. (Plenum: New York and London, 1977.) \$47.40.

DURING the past decade there has been an explosive increase in research on myelin. Now with the publication of a major book on the subject, it is possible to see why. Myelin is one of the most abundant of biological membranes constituting about 50% of the dry weight of the white matter, from which relatively pure fractions can be easily isolated by centrifugation. Such procedures are described in the book together with tabulated data of lipid and protein analysis of myelin fractions of central and peripheral nerve. Extensive biophysical data (for example, X-ray and neutron diffraction) has been correlated with the chemistry and the ingenious use of probe analysis. As a result, we probably know more about the molecular architecture of myelin than many other biological membranes.

The first chapter contains a great deal of impressive and well illustrated information on the morphology of the myelin-formative glial or Schwann cells. Although little is known about the mechanisms controlling the transition stage between glial plasma membrane and the fully mature compact myelin lamellae, the glial cell must, during the period of myelination, have a remarkable synthetic activity, for it seems to be capable of making three times its weight of myelin per day. The myelinating brain therefore provides a unique system for studying membrane biosynthesis. Some of the relevant precursor-product labelling

studies and the so far equivocal attempts at isolation of intermediary 'myelin-like' fractions from developing brain are critically discussed by different contributors.

Study of the biology of myelin is, however, of more than academic interest for in several neurological diseases there is damage to the white matter with accompanying loss of myelin. In the otherwise excellent chapters on neuropathology and neurology of myelin diseases more space could have usefully been devoted to multiple sclerosis, since this is one of the commonest neurological diseases.

Other chapters cover chemical pathology, experimental pathology and animal models of genetic myelin disorder. One of the most important features of myelin pathology relates to the pronounced immunological response to the protein antigens and lipid haptens (for example, cerebroside). This subject is especially relevant following the recent discovery of a relaxing and remitting form of experimental allergic encephalitis.

It will be evident that the whole intriguing subject of the biology of myelin is well covered in this book and it can be recommended as a readable and authoritative account of the subject.

Although the book is on a specialist subject it can be recommended to the general reader who might thereby be encouraged to utilise some of the basic concepts and discoveries on myelin in other fields of biology.

announcements

On the Move

Dr E. B. Carstens, Department of Microbiology, Centre Hospitalier Universitaire, Sherbrooke, Canada, to Institute of Genetics, University of Cologne, Germany.

Details of changes of department, sabbaticals, where leave will be taken and so on should be sent to On the Move; there is no charge for this service.

Appointments

Dr E. H. Francis, to the Chair of Earth Sciences, University of Leeds, from 1 October 1977.

Professor H. Charnock, Director of the Institute of Oceanographic Sciences, to the Chair of Physical Oceanography, University of Southampton, from 1 February 1978.

Dr P. Crutzen, to Director of the Atmospheric Quality Division of the National Center for Atmospheric Research (NCAR).

Professor R. N. Pryor, to President-Elect of the Institution of Mining and Metallurgy from 20 June 1978.

Awards

Dr G. N. Hounsfield has been awarded the Royal Society Mullard Award for 1977 (£1,000) in recognition of his conception and development of the EMI-Scanner, a computerised three-dimensional X-ray system.

Two Technology Writers' Awards, sponsored by ITT Business Systems under the auspices of British science writers, will be awarded for work published between 1 January and 31 December 1977. One will be for work published in professional periodicals, trade and technical magazines, or national and regional newspapers, the other for material broadcast on radio or television. Both prizes will be £1,000 cash and £500 for travel or equipment. All entries are by submission (to J. Anstiss, MPR Ltd, 293 Gray's Inn Road, London WC1, UK), and it is hoped to announce the winners in February 1978.

Marconi International Fellowship

Nominations, to be received by 15 October 1977, are invited for the 1978 Fellowship (\$25,000), established in 1974 to commemorate Guglielmo Marconi's contributions to scientific discovery, engineering and technology. The recipient, in recognition of out-

standing contribution in these fields, is invited to give a public lecture based on the work during the 12 months following presentation. Address all enquiries to The Marconi International Fellowship Council, Aspen Institute for Humanistic Studies, 1919 Fourteenth Street, No. 811, Boulder, Colorado 80302, USA.

National Academy of Sciences Committee on Aerobiology

A new programme has been outlined by a NAS committee to encourage the advancement of Aerobiology as a discrete science. The NAS wish to compile a register of aerobiologists, giving details of research interests. Please send relevant information to National Research Council, Assembly of Life Sciences, 2101 Constitution Avenue, Washington, DC 20418.

Meetings

30 September, **Fine Structure and Chemical Shifts in Electron Spectroscopy**, London, UK (The Institute of Physics, 47 Belgrave Square, London SW1, UK).

30 September–1 October, **Measurement in Biological Electron Microscopy**, Bristol, (Physiology Departmental Office, The Medical School, University of Bristol, Bristol, UK).

2–8 October, **2nd International Colloquium on Physical and Chemical Information Transfer in Regulation of Reproduction and Ageing**, Varna, Bulgaria (Secretariat, Colloquium '77, Central Laboratory of Biophysics, Acad. G. Bonchev Str. Bl. 6, 1113 Sofia, Bulgaria).

3–5 October, **5th Biennial Symposium on Turbulence**, Rolla (Turbulence Symposium, Extension Division, University of Missouri-Rolla, Rolla, Missouri 65401).

3–7 October, **Thermodynamics of Magnetic Fluids**, Udine, Italy (B. Berkovsky, Science Sector, UNESCO, 7 place de Fontenoy, 75700 Paris, France).

5 October, **Technology Transfer from the Nuclear Industry**, Harewell (The Meetings Secretary, The Institution of Metallurgists, Northway House, Whetstone, London, UK).

7–11 October, **VII International Congress of Essential Oils**, Kyoto (Y. Kato, Secretary General, VII International Congress of Essential Oils, c/o Kyoto International Conference Hall, Takaraike, Sakyo-ku Kyoto, 606 Japan).

10–13 October, **XXV International Meeting on Transportation and Com-**

munications, Genoa (International Institute of Communication, Villa Piaggio, Via Pertinace, 16125 Genova, Italy).

11–13 October, **4th Annual UMR-DNR Conference on Energy**, Rolla (N. Fleming, Conference Coordinator, Extension Division, University of Missouri-Rolla, Rolla, Missouri 65401).

11–13 October, **AGU Conference on Oceanic Fronts**, New Orleans (American Geophysical Union, 1909 K St, NW, Washington, DC 20006).

17–18 October, **Conference on Genetic Epidemiology**, Hawaii (N. E. Morton, School of Public Health, University of Hawaii, Honolulu 96822).

17–21 October, **1st International Congress on Phosphorus Compounds and their Non-fertiliser Uses**, Rabat, Morocco (IMPHOS (World Phosphate Rock Institute), 8 rue de Penthievre, 75008 Paris, France).

19–21 October, **Symposium on Current Topics in Drug Research**, Uppsala (R. Dahlbom, Biomedical Center, University of Uppsala, Box 574, S-751 23 Uppsala, Sweden).

24–26 October, **ASTM Symposium on Erosion: Prevention and Useful Applications**, Vail, Colo (Miss J. B. Wheeler, ASTM, 1916 Race Street, Philadelphia, Pa. 19103).

24–28 October, **International Conference on Water Chemistry of Nuclear Reactor Systems**, Bournemouth (The Conference Office, Institution of Civil Engineers, 1–7 Great George Street, London SW1, UK).

25–28 October, **International Conference—Radar 77**, London, UK (The Institution of Electrical Engineers, Savoy Place, London WC2, UK).

31 October–3 November, **Advancing Energy Technology**, Eastbourne (The Institute of Fuel, 18 Devonshire Street, Portland Place, London W1, UK).

31 October–4 November, **Symposium on Radioimmunoassay, and Related Procedures in Medicine**, Berlin (International Atomic Energy Agency, PO Box 590, A-1011 Vienna, Austria).

31 October–4 November, **Conference on Water Chlorination: Environmental Impact and Health Effects**, Gatlinburg (R. L. Jolley, Chemical Technology Division, Oak Ridge National Laboratory, PO Box X, Oak Ridge, Tennessee 37830).

2–3 November, **International Symposium on Polarography in Action**, London, UK (The Secretary, Scientific Symposia Ltd, 42–43 Gerrard Street, London W1, UK).

29 September 1977

Political will now the issue

THE Commons Select Committee on Science and Technology has recently reported on the development of alternative sources of energy for the United Kingdom (House of Commons Paper 534). With painstaking care the committee has heard evidence on tidal power, solar energy, nuclear fusion, geothermal resources, wind and waves. And yet at the end of it all one is left wondering whether the United Kingdom is going to think itself into an energy policy and, if so, whether we will be prepared to bite the bullet on the subject of alternative energy sources.

The report itself is on the whole unobjectionable. Various sources are reviewed and commented on; solar energy for space and water heating is seen as having the greatest immediate potential, and the committee recommends its vigorous exploitation. Solar electricity is given a less cheerful assessment, although the rate of development of amorphous semiconductors might well render this opinion obsolete in the near future. Biomass, which is one of the pillars of Amory Lovins' *Soft Energy Paths* (offering according to Mr Lovins "practical economically interesting technologies sufficient to run an efficient US transport sector"), is barely mentioned. Wave power for electricity generation is seen, somewhat delphically, to have considerable potential "if the technical difficulties can be overcome, and economic viability established". Wind and geothermal energy are not highly rated. And so on. A disappointment is that there is no parallel assessment of energy storage techniques which, as Martin Ryle recently argued, could make a lot of difference to the viability of some alternative-energy projects.

Technical analyses of the sort that the committee provides are now common; there are plenty of excellent books, reports and magazine articles to inform the public, and this latest document can add relatively little to what has already been put about—and what fairly quickly becomes outdated. Where those in the political arena should now be more exercised is in asking just

what alternative energy sources are for. And before such a question can be answered some distinctions need to be made between different types of alternative energy source. To include nuclear fusion in the same general category as, say wind power is clearly wrong. The former has the potential at some time in the future to take over a massive proportion of the country's energy requirements if the political will is there, the latter does not, and it seems foolish to talk about such divergent technologies under the same heading.

Some clear thinking is also needed in the near future on what will be politically acceptable in terms of import and export. It has been customary to discuss some alternative-energy technologies as worth pursuing mainly for their export potential. But the opposite side of the coin is the possibility of importing energy. The question of biomass again springs to mind. Undoubtedly the United Kingdom is not favourably situated compared with equatorial countries. Many of these countries fall into the developing category. The policy questions of independence *versus* support for the developing world *versus* fear of a future OPEC are certainly worth pursuing at this early stage.

Finally, what is the purpose of research into alternative energy sources? If in future years the source could be expected to provide, say, 5% of the UK's energy needs, does it make sense to pursue the subject? Small indentations into a major problem may be attractive scientifically and emotionally but could be trivial in the context of resource conservation or reduction in expenditure on foreign currency. Somewhere along the line this far-from-easy problem will have to be faced; on the assumption that the United Kingdom will continue to place its energy reliance on the major sources in view at the present, for how long will it make sense to encourage vigorous research in the small alternative sources? The question would, of course, be very different if we were to move to a 'softer' path, but on that there seems as yet to be no political discussion. □

BA address: Huxley responds

Sir Andrew Huxley, Royal Society Research Professor in the Department of Physiology at University College London, responds to Nature's editorial on the presidential address he delivered to the recent British Association meeting

SIR,—Your editorial (8 September) about my presidential address to the British Association misses the point of what I said on the relations between human values and scientific research. I discussed this matter in several contexts—evolution; paranormal phenomena; the Lysenko controversy; and the inheritance of human ability. You mention only the last, and you write as though I had simply called for more research in this field. You have misread me. What I was urging was that the conclusions of whatever research is done should not be biased by preconceptions or by external pressures. In recent years, this issue has been bedevilled by strong pressures, which in Europe and in most of the USA have come almost exclusively from those who insist that the genetic component is negligibly small. These pressures have taken forms which I hope you agree are improper—the baseless insinuation that there is necessarily something 'racist' in admitting the possibility of a genetic component; denial of freedom of speech; and physical attacks. It is easy to imagine similar pressures being exerted by others in the opposite direction; if this occurs I shall resist them just as forcibly, but as far as I know this has not been happening, at least in Europe, since the defeat of Hitler.

I did not say much about the good that might come from an increase of knowledge on the causes of differences in ability, partly because this was not the subject of my address, partly because I am no expert in these matters but also because I did not wish to buy off opposition to my main thesis by playing down the risk of uncomfortable passages ahead if, in any field, we allow evidence to be collected and published. In my view the independence of Science is something that should be accepted irrespective of the consequences that may appear to us to be likely. Human affairs are so unpredictable that it is more probable that good will be done by letting our beliefs follow from the evidence, than by deciding without the evidence what beliefs will lead to the best actions. Since you challenge me, however, I will set out some of the ways in which increased knowledge could do good.

You say "Questions are bound to be asked about motives for doing more research, especially as there is little doubt that inheritance does play at least some and maybe a very significant part in the acquisition of ability". One answer—already given in my address—is as follows. If inheritance plays no significant part, long-term policy need only aim to provide equal opportunity and to eliminate prejudice based on class and race. But if its role is "very significant", we must also build into our system compensatory advantages for groups who would otherwise feel excluded from a fair share of well-rewarded and respected occupations: 'affirmative action' as in the USA would be a step in this direction but other measures might be needed as well—perhaps for example up-grading those jobs which have the lowest requirements in scholastic attainment. Such policies would naturally be resented by the groups whom they do not favour (witness the case of Allan Bakke now before the US Supreme Court) and probably ought not to be vigorously implemented unless it is clear that a substantial genetic

component exists.

A second way in which further investigation could be valuable is the following: if there are no appreciable genetic differences, the best way to establish the fact will be to carry out genetic investigations. An example is that Shockley's approaches to the National Academy of Sciences in the United States led indirectly to a review of the position being undertaken under the auspices of a committee of the US Social Science Research Council, and the resulting book (J. C. Loehlin, G. Lindzey & J. N. Spuhler, *Race differences in intelligence*, W. H. Freeman & Co., 1975) gives prominence to two interesting genetic investigations, one based on correlation of IQ with blood groups in persons of mixed ancestry, and the other on the performance of illegitimate offspring of Negro and White US servicemen with German women during the occupation of Germany after World War II. Neither of these gave any support for a simple genetic difference between Negro and White.

Yet another reason to wish for greater knowledge is that, as understanding improves, so emotional reactions will become less. Suppose, for example, that a gene were indentified which, like the sickle-cell gene, confers some resistance against a tropical disease but whose compensatory disadvantage in the homozygote is a moderate drop in scholastic ability instead of a haemolytic disease: I believe this would be regarded purely as a piece of misfortune to those affected and in no way as a matter for shame.

It would be idle to suggest more specifically the way in which improved knowledge and understanding might be valuable. The chief characteristic of research is that its outcome is not known in advance. A large part of my address was devoted to examples where the progress of science was held up by a false assumption that a result could be deduced by extrapolation from what was already known. This part of my address you dismiss as "a lengthy aside", but it is highly relevant to the question of the causation of differences of ability. Our understanding in this field is still in a primitive state, and I would guess that there will be several unforeseen changes of view on both the environmental and the genetic side before an agreed position is reached. Meanwhile, what is needed is, on the one hand, for policy-makers to be conscious of this uncertainty, to be guided largely by humane considerations and by common sense rather than by predictions based on particular theories, and to avoid decisions liable to be harmful if unsuspected factors turn out to be at work. On the other hand, research should continue, with as little bias as can be attained and without premature claims on either side to have reached a final solution.

I retain a conviction—difficult no doubt to justify rigorously in each individual case—that an improvement in our understanding of a problem will in the long run improve our attempts to solve it. I find it deeply depressing that you, the Editor of the leading general scientific journal of the whole world, should in your final sentences tell us in effect that, in any field which is important enough to generate emotion, we ought not to undertake research until we are sure that its conclusion will be to our liking.

ANDREW HUXLEY, FRS

The full text of Sir Andrew Huxley's address appeared in The Times Higher Education Supplement of 2 September

Desertification: another mirage?

Robin Sharp reports on the UN Conference which ended in Nairobi earlier this month

DESERT rash is an ugly dermatitis which spreads in blotches and peels off bits of the world's skin. Having diagnosed it, traced it to no fewer than 45 sources and called it desertification, the United Nations has this month successfully patented a selection of medicines to control and cure the disease.

The UN Conference on Desertification (UNCOD) was very much a synthetic event, in the best sense of the term. Neither a scientific nor essentially a political gathering, it sought to bring together a range of disciplines and socio-political interests to create a new holistic approach to the problems of desert rash in the world's dry lands. The conference did not pretend to be inventing a new branch of science but rather a new conceptual framework for research and policy-making. Judging by the high degree of consensus among the 90 countries present on the ailment and its cure, this seems to have been achieved.

One danger with a newly-identified problem is that people too readily assume it needs new-fangled solutions. In the case of desertification, the teams of experts who produced the basic conference documents were cautious enough to recognise modern technology as one of the hazards as well as the hopes. Because of their fragility, the principal document noted, dryland ecosystems are particularly vulnerable to misapplied technology; and in the developing countries where acceptance by the local community is a critical factor, modifications of existing technology and practice are more likely to be effective than radical innovation.

In their official conference paper, 'Ecological change and desertification', Andrew Warren and Judith Maizels of University College, London, also warn that stories of technological success in dryland agriculture "should not be accepted complaisantly". Fifteen million hectares of land have been irrigated along the Indus River in Pakistan, for example, but an estimated two-thirds of this vast area is now affected by consequent waterlogging and salinisation.

The conference was presented with three other 'component reviews' covering technology, climate and human and social factors. All four were then summarised in an overview report, which

provided the basis for the first part of the conference debate. In fact, apart from various nuances and some disagreement over whether and how to define the neologism coined for the conference title, there was little dispute over the secretariat's analysis of the causes and effects of desertification.

Bone of contention

The only real bone of contention was whether or not, as averred by Dr Mostafa Tolba, the conference Secretary-General, "man now has in his possession both the wealth of knowledge and adequate technical means to bring desertification to a halt and, in many instances, to reverse the process". The overview paper emphasised the same point, asserting that the knowledge and experience to tackle most aspects of the problem was "available right now".

This, however, was not good enough for the six national and regional science associations which held a seminar in Nairobi immediately before the conference to feed in their views. In their opinion it reflected an implicit overconfidence in the adequacy of existing technology, not to mention an underestimation of the human and economic costs which in the short-term could well rival the costs of the problem itself.

Both concerns drew attention in the debate, a number of countries pointing out that more basic and applied research was still needed in areas such as water harvesting, rainfall prediction, water desalination, alternative energy sources and water-crop relationships. Several delegates stressed the need for intensified efforts in the field of climatology and a closer working relationship between climatologists and agriculturalists at various levels.

One experiment which may eventually enable climatological events to be predicted in the world's dry regions is to be launched next year by the World Meteorological Organisation (WMO). Under its Global Atmospheric Research Programme (GARP), run jointly with the International Council of Scientific Unions, the WMO will make detailed worldwide observations of the atmosphere over a 12-month period. It is described as the largest scientific experiment ever undertaken internationally for peaceful purposes, using satellites, aircraft, ships, balloons and Press handouts, so they'd better come up with something.

Plan of action

After agreeing that desertification has many causes and that most are man-made, the conference then moved on to consider what could be done about them. Though most of it may be no more than a set of guidelines for any government caring to take note, the UN conference formula these days makes it *de rigueur* to produce a 'plan of action'. And as these things go, the desertification action plan went pretty well. It recommended careful assessment and monitoring of the extent of desertification, proper management of water resources, rangelands, livestock and wildlife, urgent measures to overcome the loss of water and land caused by irrigation, special steps to improve soil conservation, national land-use planning, and—just to make sure that nothing was left out—"national systems for monitoring the human condition".

Focusing on the developing countries, the 'plan of action' called for measures to strengthen indigenous capabilities in science and technology, paying special attention to the rational use of dryland resources. This might include setting up or strengthening national scientific institutions concerned with desertification. The plan further urged that research be vigorously pursued on cheap alternative energy sources which could help to halt the alarming rate of deforestation caused by the pressure of demand for firewood in many dry countries.

Pilot project experiments could be set up to test the use of wind energy for generators and water pumps, and solar energy for water heaters and distillers, cookers, food dryers and refrigerators. On all these points the conference anticipated further action at the second UN Conference on Science and Technology to be held in two years' time.

The need for public awareness campaigns to educate people in general and dryland populations in particular about the sustainable use of their environment was emphasised by a number of countries. As the Australian delegation put it, the people contributing to the problem must be made aware of its existence and causes. On another tack, the Australians were scathing about the special desertification map produced for the conference. Not only did it contain serious errors, but at a scale of 1:25,000,000 it wasn't going to be much help and in any case the validity of mapping a set of dynamic processes was questionable.

Less than enthusiastic

For similar reasons, they were less than enthusiastic about the use of information from remote-sensing satellites as an anti-desertification tech-

nique. Out of six transnational feasibility studies drawn up for the conference, two were devoted to the monitoring of desertification in south-west Asia and South America by Landsat imagery, using the Earth Resources Technology Satellite (ERTS). The use of satellite imagery thus came in for quite a bit of notice, but the Australians and others thought it had aroused "excessive expectations" and reckoned that for most purposes 'ground truth' observations were a much better bet.

The transnational feasibility studies were commissioned as the basis for possible inter-governmental agreements on large-scale regional projects to combat desertification. Apart from the two remote-sensing schemes, the studies provide for the planting of 'green belts' north and south of the Sahara, the management of livestock and rangelands in seven countries of the Sudan-Sahelian region, and management of the major regional aquifers in north-east Africa and the Arabian Peninsula. Though challenged on grounds both of cost and effectiveness, the Secretariat was able to claim that several governments had already signified their readiness to go ahead.

Inevitably in the volume of research amassed for this meeting there were a number of inconsistencies, plus a few worrying omissions. At some points in the documents and the debate, the need of developing countries for simple, low-cost technologies was carefully stressed, but elsewhere sophisticated remedies were advanced without much evidence whether those to whom they were addressed could or should afford them. Likewise, it was acknowledged that desirable changes in traditional farming and other forms of land use were subject to important economic, social and cultural restraints. Yet when it came to calculating how readily the threatened drylands would respond to the conference's action package, the implications of this seem to have been overlooked in favour of more measurable financial, scientific and administrative criteria.

Two omissions

Two significant factors in the desertification process were glossed over in Nairobi, intentionally or otherwise. Firstly, though the UN Food and Agriculture Organisation (FAO) has a conference on land reform scheduled for next year, the degree to which feudal or other land tenure systems still contribute to desertification in several countries—for example erosion caused by peasants forced out of the valleys to farm marginal slopes—was studiously ignored. And again, no one asked aloud whether those governments determined to get their nomads settled

Marginal living on the Saharan fringe

down had analysed the long-term consequences of demobilising the people best equipped to balance the economic potential and the limitations of life on the desert margin.

Perhaps the secretariat was a bit too anxious not to ruffle any political feathers. In any event, for better or worse, this was one of the least politicised UN meetings in recent times. Apart from an Arab move obliging the conference to pretend that Israel's impressive record of desert reclamation did not exist, the proceedings were remarkably free of ideological entanglements.

Of course there had to be a bit of a crunch at the end, and, not surprisingly, it centred on cash and administrative machinery for the post-conference follow-through. True to form, the industrialised countries came out against the creation of any new international body for desertification which they might have to pay for. They were having nothing to do with the notion of an international tax to help finance the 'plan of action', and Dr Tolba knew the odds when he conceded at the start that there might be "some problems" in attempting to set up another Special Fund for the purpose.

In the end, as everyone expected, the follow-through responsibility was handed over from Dr Tolba, Secretary-General of the conference, to Dr Tolba, Executive Director of the UN Environment Programme. For whatever apprehensions there might be in various capitals about UNEP, it was the cheapest, neatest, most logical answer—and Dr Tolba was generally acknowledged to have done a masterly job in getting the show on the road.

So from its barrack-like HQ on the outskirts of Nairobi, enlivened with

outdoor murals of wallowing hippos and the like, UNEP will now have the task of pulling all the other UN agencies together to work out uniform methodologies, to coordinate and expand their research efforts on desertification and to build a solid organisational structure inside the conference's conceptual scaffolding. A mammoth task, one might say, but there's no doubt much has been accomplished in the two years leading up to the conference.

Not too disappointing

By the time UNDP, UNIDO, FAO, UNESCO, WMO, WHO, the World Bank and others have reshuffled their budget headings to make room for this new arrival, even the present level of spending to combat desertification will probably not look too disappointing, given the many competing development priorities. And it should be worth much more if and when all the bits are linked into a concerted programme. Added to this, according to one estimate, are 15,000 or more researchers and 300 institutions around the world already involved in arid-land research.

With resources on this scale available to be mustered in a global campaign, the prospect of halting and pushing back the deserts might appear no longer a mirage. But there's still one more snag the conference tended to forget. By the year 2000, when the 'plan of action' is due to be fully implemented, the population of the world's drylands, now around 600 million, will be up to 1,000 million or more, with all the concomitant pressures this will bring. Those charged with the problem may therefore find themselves having to run very hard just to stand still. And come to think of it, that is a bit like chasing a mirage, after all. □

BRITAIN

Discomfiting prognoses

The UK Science Research Council (SRC) published its latest annual report last week. Chris Sherwell outlines some of the difficulties

BRITAIN'S Science Research Council sees itself as the country's only supporter of 'big' science. Research in high energy physics, astronomy, space and geophysics, it feels, would collapse if it withdrew its funding. The SRC is not about to pull out of these fields. But the pressure over the past few years to cut back has now reached such a pitch that the SRC believes it may not be able to discharge its responsibilities adequately by the early 1980s. Much now rests on whether some sort of turn-round materialises in the next couple of years.

Last week's report*, covering the twelve months to March this year, continues to promote the image of unrelieved gloom that has become familiar in recent years, and in some respects offers even more discomfiting prognoses. Some idea of the worrying trend appears in the accompanying table, showing how the distribution of SRC expenditure will change. But the report also spells out in cold terms what is called the "best disposition" for big science over the coming years.

Nuclear physics expenditure, for example, will run down more steeply, at 6½% a year instead of the 5% planned last year. The £43.5 million to be spent this year will fall to £33 million by 1981-82, of which fully £20 million will go on the CERN subscription. This level of support, says the SRC, is inadequate to continue the full exploitation of existing facilities, and will not permit the full use of the nuclear structure facility at Daresbury or allow British participation in any future international high energy facility.

The more important question for now, however, is whether this level is below the 'minimum viable level' of support which became common parlance by last year but which went largely unspecified. That it is lower than forecast is certain; but different views will abound on whether in the process the minimum level has actually been breached or simply redefined. The high energy physics community's argument for the former would presumably be dampened by a more efficacious use of the CERN facilities.

Astronomy and geophysics fare

even worse than nuclear physics. Expenditure of £28 million this year, which the report says is 14% down on last year, will fall further still to £23 million in 1981-82. Space expenditure outside the ESA subscription (which remains at £8 million in all years) will fall from something like double that subscription to two-thirds next year and one-half by 1981-82. The report says this means proper advantage cannot be taken of opportunities through ESA and the use of the Space Shuttle and Spacelab.

The corollary, however, is that the domestic programme suffers. Such are the consequences of tight money that this obviously threatens to raise questions about the value of organised international efforts in space research. The alternative would be *ad hoc* use of US facilities. No one is saying publicly that Britain is even close to this position. But the signs are that such a state of affairs could loom in the future.

One comparatively bright spot focuses on the special programmes in the areas which the SRC has selected for support because of their national importance. Three in particular—the Teaching Company Scheme, Marine Technology and Polymer Engineering—collect a 25% increase from £14.5 million in 1977-78 to about £18 million in 1981-82.

A reminder of the sort of problems that big science projects pose is contained in the report's review of the Science Board's work. The Board is experiencing them for the first time with the conversion of Nimrod, the proton synchrotron at Rutherford, to a spallation neutron source—one of the SRC's now famous attempts at cannibalising existing facilities to save money. The Board chairman, John Jinks, says control of year-by-year expenditure was simple and policy was quickly effective when research grants were its main activity; with central facilities, on the other hand, long-term financial commitments, quasi-permanent operations and established staffs mean that delays are the only

way to economise, and this can vitiate the usefulness of the research.

How far the SRC has gone along the immensely fruitful line of cannibalising existing facilities is not certain. Plainly, though, the need to do it depends on financial exigencies. International subscriptions, which form some 30% of the SRC's total expenditure, are fixed; with the international value of sterling beyond SRC influence, and expenditure subject to the Treasury's cash limits regime, the SRC lacks control over a sizeable fraction of its outgoings. Couple this with inadequate compensation for increased student grants and for subscriptions, mix in the effect of public expenditure cuts last year and those planned for coming years, and the SRC has a recipe for lower expectations. What makes the fare unsavoury is the higher number of qualified candidates for studentships for whom lack of support means lost opportunities for advanced training.

A pick-up in the British economy is one way the outlook might theoretically improve. Other more logical and practical ways, at least from the SRC's point of view, include a greater commitment to the country's research effort on the part of the government, and a greater commitment to the SRC rather than the other research councils on the part of the ABRC. If there is cause for hope on the latter two of these fronts it may indicate an incipient 'backlash' effect following the SRC's past acceptance of negative growth rates (now -1.7% until 1981-82). The SRC wants a constant budget to do a competent job, and to achieve that between now and 1981-82 it says it needs £25 million. But as yet this would demand a turn-round in policy as well as a turn-round for the economy.

● In a display of acute deadline consciousness, the appointment of Professor Geoffrey Allen as chairman of the Science Research Council has, after an unusually lengthy delay, been confirmed by Shirley Williams, the Secretary of State for Education and Science. The four-year appointment, which takes effect this coming week-end, first became known in March this year, and followed press reports that included names of certain individuals who had allegedly been approached for the job and turned it down. The usual need for clearances contributed to the delay, but administrative hold-ups and the publicity that surrounded the selection did not help.

Professor Allen takes over from Sir Sam Edwards, who takes on a part-time appointment as chairman of the Defence Science Advisory Committee.

COMECON

● A team from the Warsaw Institute of Plasma Physics and Laser Fusion, headed by Professor Sylwester Kaliski, Poland's Minister for Education and Science, has achieved the generation of neutrons by thermonuclear fusion using a concentric explosion with an exceptionally high degree of symmetry. The result was announced at an international conference in Prague last week and received considerable eve-of-conference publicity on Polish radio and television. According to the broadcast, this is the first published result of neutrons from thermonuclear fusion being obtained by pure explosion. The broadcast spoke optimistically of "extending the process to a commercial scale", but the figures indicate the production of only 3×10^7 neutrons from 10^{-7} g deuterium, and it is estimated that a level of some 10^{17} neutrons would be required for commercially viable thermonuclear power generation.

● It is reported from Poland that, in spite of the amnesty of last July, repressive measures are still being taken against supporters of the Workers' Defence Committee. The WDC was set up a year ago to defend the rights of the Radom and Ursus workers suffering reprisals for their part in protests against soaring food prices. During the next few months, a number of WDC members, including several scientists, were themselves subjected to repression, but support for the WDC grew. At the beginning of June, a group in Wrocław, mostly from higher academic institutions, sent a letter to the government criticising the press campaign against the WDC and urging that sanctions against WDC members be withdrawn.

A letter to the WDC now claims that shortly afterwards reprisals began against the signatories. Three lecturers, including Dr Eugeniusz Porada, a mathematician, lost their jobs, ostensibly for trivial administrative reasons. The letter was signed by Professor Stanisław Hartman of the Mathematics Institute of the Polish Academy of Sciences; he and Professor A. Duda have been relieved of their posts as consultants to the special mathematics courses for gifted young people, founded in 1973 in several university cities.

● Last month, the supervisors of the Comecon Departments of Inventions met in Ulan-Bator, Mongolia, to discuss the problems of patent protection within the Comecon bloc. Until the late 1950s, the Comecon countries somewhat neglected the protec-

tion of inventions and innovations; since then, the position has changed so much that now even minor factory modifications are granted a patent or its equivalent. However, a survey of Comecon patent law, published in Warsaw in 1970, revealed considerable discrepancies in practice between the various countries. Thus, in the

USSR and Bulgaria, an 'author's certificate' gives unlimited protection; in most Comecon countries, the patent protection is for 15 years, in East Germany 18 years and in Hungary 20 years. The invention must be used within two years of its being reported in Hungary, and within three years of the granting of the protection in Poland; in the USSR there is no obligation to use an economic patent at all. In 1971, the Conference of Supervisors of Departments of Inventions was established to promote cooperation in the field of patents and to eliminate such anomalies.

The twelfth meeting of the conference, which was opened recently by the Mongolian Deputy Premier, S. Luvsangombo, and chaired by the Deputy Chairman of the Mongolian State Committee for Science and Technology, presented a promising picture of work in hand. A progress report was presented on the co-ordination of draft agreements on mutual legal protection of instructions of origin and designation of origins of commodities. A model bilateral agreement on conducting patent investigations was approved. Special attention was paid to problems of "rationalising" the economy, including the work of "rationalisers" within the framework of international economic organisations and a model system for handing over rationalisation proposals as part of scientific and technical cooperation agreements.

● One important element in Comecon integration plans is computerisation of both production and planning. As far as the production of components is concerned, the computerisation plans seem to be going forward well. Bulgaria has recently built up with Soviet aid a flourishing electronics industry, and last year earned more than 480 million foreign-currency leva from exports.

When it comes to the introduction of computers into the Comecon economies, however, the picture is less rosy. In Czechoslovakia, for example, the predominant trend so far has been the construction of data-processing systems for individual factories. These facilities, however, have been grossly under-used, the factory computers often simply recording data which is not applied in subsequent management and planning decisions. Recent figures from the Czechoslovak Federal Statistical Office indicate that on occasion factories have not used as much as two-thirds of the available machine-time, but either sold it to other consumers, or else simply wasted it. Accordingly, greater emphasis is now being placed on the construction of combined data-processing centres.

● Anti-pollution measures have recently been commanding a great deal of attention throughout the Comecon media. Thus Bulgaria, which recently introduced a set of "Basic Guidelines for the Conservation of the Environment", is to spend 78 million leva in Sofia *okrug* (county) alone, mainly on water-treatment plants on the Iskar, Maritsa and Topolnitsa rivers, and on equipment to remove toxic gases from the air. This is clearly a matter of some urgency—last year in the Sofia *okrug* 106 industrial, economic and commercial enterprises had to be closed down, 25 of them permanently, for violating public health requirements.

In Hungary, air pollution surrounding the Metallokema works at Nagytetyen has been causing concern since the middle of April. Complaints from local residents indicate that household pets were dying and fruit, vegetables and window-sills were covered with a greyish dust. In addition, three small children had to be treated in hospital for lead poisoning: an investigation by the local health authorities showed that the lead content of the atmosphere was 30–40 times the permitted level, and on 30 June the factory was ordered to close. The order was ignored.

Vera Rich

IN BRIEF

JET: Costly hold-up?

Confirming the loss of members of his group to the United States, Dr Paul Rebut, the French scientist who heads the design team based at Culham working on the European fusion project JET, was quoted as saying last week that even if a decision on the site of the next stage of the project was taken now, it could take up to a year to re-form the team.

Dr Rebut's comments, in an interview with the *Oxford Mail*, followed the news that the EEC Council of Foreign Ministers had not even discussed the subject, let alone come to a decision, when it met last week. The subject did not appear on the agenda because meetings between representatives from

Britain and Germany, the countries with the strongest candidates for the siting of JET, had not taken place as planned since the last Council meeting in July. A high level Anglo-German meeting in Bonn set for 9-10 September was cancelled because of the kidnapping of Hans-Martin Schleyer. The ministers will meet informally on 8-9 October, and formally on 17-18 October.

NERC report, appointment

Like the UK SRC, the Natural Environment Research Council (NERC) last week published its report for the year to March 1977 and acquired a new chairman. A feature of the report is a

6-page description of the contribution NERC research can make to solving problems of energy and the environment; in particular, on the controversial issue of disposal of high-level radioactive waste, the report says the funds needed are "many times greater than the very modest sums" with which NERC is undertaking current studies.

The report also shows that the main bulk of the £26.675 million spent on NERC's scientific programme went on studies of the earth (42.2%) and the sea (32.9%). Commissioned research totalled nearly £15 million.

The man who will succeed Sir Peter Kent as chairman of NERC is Professor J. W. L. Beament, the insect physiologist.

MANY observers thought that the 1972 United Nations Conference on the Environment, in Stockholm, Sweden, was marred by the evident differences of opinion between the rich and poor nations on their priorities. The delegates from the so-called developed countries in Europe and North America were enthusiastic about controlling pollution (even when their governments were not always effective in carrying out these intentions). Many speakers from the poorer countries, now optimistically called 'developing', said that increasing their productivity and raising the standard of living of their citizens was more important. They pointed out that Britain and other comparatively wealthy countries had done little to control pollution during their industrial revolution, in the nineteenth century, and to impose unrealistic and expensive standards on those who were just setting out on the same road would hold them back unnecessarily.

It is encouraging to find that this view is not universally held. I am just back from Mauritius, where I was invited by its government to advise on environmental problems and their control. Mauritius, known to many only as the former home of the extinct dodo, and the place where the most valuable postage stamp was printed, is a volcanic island in the middle of the Indian Ocean. It covers some 760 square miles and has over 800,000 inhabitants. It was first a Dutch and then a French colony, until captured by the British in 1810. It remained a British colony until 1968, when it became an independent state, a member of the Commonwealth. Its main income is from sugar, and some 54% of the island's surface is covered by sugar cane. It

is a net food importer, and attempts to reach greater self-sufficiency by the diversification of agriculture are being made, though little good land remains uncultivated. Industrial development, particularly of light in-

Dirty development

KENNETH MELLANBY

dustries, has recently made some progress, and is said to produce nearly a quarter of the island's income.

As yet Mauritius has no really damaging pollution problems. It would be hard to produce serious air pollution in a small oceanic island in the region of the trade winds. There is some smoke from factories, dust from stone crushers, and road safety is often impaired by the smoke screens from badly maintained diesel lorries and buses. The beaches of white coral sand, the main tourist attraction, are clean except near settlements and sewage outfalls. How-

ever, there are many at present trivial nuisances which could soon grow into environmental dangers. Refuse, likely to increase with population and a growing GNP, is seldom collected and never dealt with hygienically. Much is thrown into streams, the one place where the maximum damage will occur. Factories are surrounded by noisome piles of uncollected debris. Some people exhibit a genius for doing the most damage with the smallest amount of a pollutant. Thus a small tea factory in a sparsely inhabited hilly area has a leaky pipe from its oil tank. A few gallons seep out each year into the adjoining stream, half a mile above the intake for the local water supply. Garages always seem to empty their used sump oil into the nearest river.

Thus with a growing population, rising incomes and more industry the future for Mauritius could be a dirty one, unless immediate steps are taken to preserve the environment. Some encouragement can be obtained from the sugar industry, which could be a major polluter. The largest and best-run factories have remarkably little harmful impact on the environment, and the others are improving. The industry clearly knows what needs to be done. None of the other problems is insoluble—and success will be easier the sooner vigorous action is taken. In all developing countries prospects are better than they were some years ago. The most valuable aid that the developed countries can give is knowledge of how they have got over the abuses of the nineteenth century. They must show that with modern industrial development, pollution control need not be unduly expensive, and that early action can be an excellent investment.

correspondence

Europe versus itself

SIR,—With reference to the editorial "Million-dollar problem—billion dollar solution?" (14 July, page 89), the problem of sulphur pollution is not a problem of Norway versus the United Kingdom, but rather of Europe versus itself.

The OECD study, to which the article refers, has shown that there is a more or less continuous export and import of pollutants between European countries and that the problem is not confined to any two countries. Nor can it be solved by individual national control programmes. It should also be emphasised that the problem is not predominantly confined to the effects of acid rainfall on fish populations. The effects of sulphur pollution fall into four main areas: human health, vegetation, the fresh water ecology, and corrosion of metals, painted surfaces and other materials.

It is established that several categories of human disease are linked to the occurrence of sulphur dioxide and associated pollutants in the atmosphere. Governments' efforts to improve the quality of the air so as to provide better health protection are likely to have the reduction of sulphur emissions as one of their main targets.

With regard to corrosion we know that material damage due to sulphur pollution in Sweden and the United States cost between \$5 and \$10 per capita per year in the early 1970s. We know that damage is inflicted on vegetation in areas polluted with high concentrations of sulphur. It is also suspected that the dispersion of sulphur will result in decreased tree growth in areas with relatively low average concentrations of pollutant. The economic consequences of such effects can be highly significant.

We must also expect synergetic or combined effects in wide areas within Europe where various harmful pollutants are dispersed through the atmosphere. Efforts should now be directed at developing a coordinated European policy for reducing emissions. The costs involved will, it is true, be formidable. Only gradual improvement can therefore be expected. The result, however, will be beneficial to health, to materials susceptible to corrosion and to the quality of the natural environ-

ment all over Europe, with particular benefits accruing to people and areas closest to emission sources.

Yours faithfully,

ERIK LYKKE

Ministry of Environment,
Norway

Nutrition in food policies

SIR,—Blythe and Rush (4 August, page 386) outlined the state of the cautious dialectics of a UK food policy which incorporates nutritional criteria. The arguments are complex and controversial, not least because of the range of disciplinary interests involved. Three of the arguments referred to by the authors warrant further comment.

First, is the search for 'absolute proof' of causal linkages between dietary constituents and diseases necessary before recommendations commensurate with formulating food policy can be made? Is 'absolute proof' actually attainable? The scientific method sets out to falsify theories through experimentation, never to prove their validity, it is neither the intent of the method nor logically possible to prove the validity of theories, irrespective of the number of experiments. Thus, the argument should be concerned with the degree of confidence that can be attached to the corroboration between theories and observations in scientific experiments. Thus, for example, where there exists a sustainable conjuncture that a particular level of dietary fat (or saturated fat) is detrimental to health, this should be sufficient basis for a recommendation.

Second, the lack of an explicit food policy which links nutrition and health to food supply is tantamount to accepting, by default, that the fragmentary components of existing policies which affect food consumption adequately accommodate nutrition and health goals. Equally, the nutrition and medical professions, by failing to make recommendations, are by default condoning the present dietary trends.

Concerns that the introduction of nutritional goals into agriculture and food supply policy would require significant structural changes are exaggerated. The food supply industry is not static: at present there is a programme

for expansion of UK agriculture, and for further structural change within the EEC. There is no reason to believe that the changes needed to include nutritional goals would be any greater than those already under discussion or being implemented for sectional economic interests alone.

Thirdly, the controversy surrounding state intervention in consumers' freedom of choice through a food and nutrition policy is a red herring. The extent to which a real freedom of choice exists is academic, but it is evident that consumers' choice is directed by a wide range of measures from diverse sources. Effectively, consumers are free to choose from numerous, but pre-determined, alternatives, and that choice is further constrained by such factors as their income, access to information, and susceptibility to advertising. A food and nutrition policy would not necessarily impose further restrictions on choice, but could provide the consumer with a more rational and coherent basis for his choice. This implies that all consumers have access to a nutritionally adequate diet with established health safeguards, while maintaining the widest feasible variety and availability of foods. As a wide access to relevant information on nutrition, health and foods is a component of most conceptions of a food and nutrition policy, it can be argued that such a possibility would increase the consumer's capacity to exercise a free choice, rather than reduce it.

Yours faithfully,

C. J. ROBBINS

Crater good

SIR,—I shall say an Ave Mare for the soul of David W. Hughes (15 September, page 197).

Yours faithfully,

L. ROSE

Leicestershire, UK

Correction

In T. R. C. Boyde's quoted derivation of the word 'enzyme' (15 September, page 194), the Greek for 'in yeast' should have read *ενζυμη*, not *ενζυμη*. The modern Greek would read *ενζυμοσ*.

news and views

The ultraviolet sense in flies

from Jonathan Ashmore

MANY insects can detect light in the near ultraviolet. So also can humans but there are problems in explaining the much greater insect ultraviolet sensitivity in terms of what is known about the visual pigments. Rhodopsin is probably one of the most intensively studied membrane proteins, yet great gaps exist in the description of the chain of events starting with the photoisomerisation of the chromophore 11-*cis* retinal and ending with the signal appearing in the nervous system. But in both vertebrate and invertebrate systems the chromophore has always turned out to be retinal, the aldehyde of vitamin A. The peak absorption wavelength λ_{\max} for those rhodopsins which have been studied either in the membrane or in solution lies in the range 460 nm to 535 nm. Free retinal has a λ_{\max} of 378 nm, and its association with the protein by way of the usual protonated Schiff base would tend to move λ_{\max} to longer wavelengths only.

However, the insect ultraviolet peak measured in the photoreceptors of a number of species both by electrophysiological and microspectrophotometric methods occurs around 360 nm. A pigment from the moth *Ascalaphus* has been isolated by Hamdorf and co-workers (*Nature* **231**, 438; 1971) with a λ_{\max} at 350 nm and retinal as the presumed chromophore, but the matter is not settled there. In rhabdomeres R1-6 of the dark adapted dipteran ommatidium, spectral absorption peaks not only at 500 nm but also in the ultraviolet. The precise wavelengths are species dependent, but the ultraviolet absorption has peculiarities: the phenomenon appears to be fairly labile, varying from cell to cell and may even change seasonally (Horridge & Mimura *Proc. R. Soc. B* **190**, 211; 1975). Since its first description 15 years ago it is still not clear whether one or two pigments are present. The sharp angular sensitivity of the receptors seems to rule out the possibility

that there is coupling from the specifically ultraviolet receptors R7 and R8.

On page 386 of this week's issue of *Nature* Kirschfeld *et al.* sidestep the one/two pigment issue by suggesting that the ultraviolet sensitivity of dipteran photoreceptors may be due to a mechanism similar to that used to extend the spectral sensitivity of photographic emulsions. Performing the microspectrophotometry on rhabdomeres R1-6 of the housefly *Musca*, they extend the earlier work on *Calliphora* by Langer and Thorell (*Expl. Cell. Res.* **41**, 673; 1966) to show that although the ultraviolet peak occurs in absolute absorption spectrum there is no conspicuous change in the ultraviolet extinction following adaptation by ultraviolet light. Such a change is virtually a prerequisite for the presence of a rhodopsin-like pigment, and special mechanisms need to be invoked to explain its absence.

The first relatively stable reaction product of rhodopsin following the absorption of light is metarhodopsin. Insect metarhodopsins are distinguished by the large redshifts of the absorption peak relative to rhodopsin. In *Musca* the effect of absorption of ultraviolet light seems to be the production of only the metarhodopsin with λ_{\max} of 580 nm which is that formed from the blue-absorbing rhodopsin with a λ_{\max} of 490 nm.

Where is the ultraviolet light being absorbed? The new technique which has been used to study the mechanism further is electrophysiological. Pak and Lidington (*J. gen. Physiol.* **63**, 740; 1974) reported that the fast potential elicited by short intense flashes of light with external recording from the photoreceptors is proportional to the metarhodopsin concentration. This provides a direct assessment of the pigment state, whereas earlier work relied on the slower receptor potentials where several stages of transduction are involved before the electrical signal can be measured. Kirschfeld *et al.* find in *Drosophila* that those flies fed a vitamin A deficient diet have a lower ultraviolet quantum efficiency com-

pared to blue light than those flies raised on a vitamin A enriched medium. The method used can now leave little doubt that the vitamin A deficiency alters in some way the efficiency of ultraviolet light absorption at the level of the visual pigment itself. Species differences in visual performance between various dipteran species have been noted as a result of vitamin A deprivation (reviewed by Stark *et al.* *Naturwissenschaften* **63**, 513; 1976), but the differences between *Musca* and *Drosophila* are probably not significant here.

The novel explanation offered for these observations is that a photostable pigment is present in normal flies which absorbs in the ultraviolet and transfers energy to the chromophore on the rhodopsin molecule. Although vitamin A deficiency may be working by reducing the rhodopsin concentration (see for example Harris *et al.* *Nature* **266**, 648; 1977), the primary effect must be the reduction in retinal and its derivatives. A vitamin A derivative is thus a likely candidate for the photostable pigment postulated, presumably membrane-bound in view of the sensitivity of these receptors to the plane of polarisation of ultraviolet light (Horridge & Mimura *op. cit.*). Cattle rhodopsin has in fact been prepared artificially with two retinals bound and has a double absorption peak, one in the ultraviolet (Rotmans *et al.* *Biochim. biophys. Acta* **357**, 151; 1974). Functional studies of such a system have not been made but it is known that fluorescent probes can be attached to sites on the rhodopsin molecule (Wu & Stryer *Proc. natn. Acad. Sci. U.S.A.* **69**, 1104; 1972) whose behaviour suggests that the kind of energy transfer required to explain the insect data may be possible given a suitably close pair of sites.

Although not based on radically new data, the suggestion of a 'sensitising pigment' may be the solution to old problems. Further developments including a more direct attack on the protein chemistry involved should tell whether it is right. □

Interferon action revisited

from Paula M. Pitha

INTERFERONS are species-specific cellular glycoproteins synthesised by a wide variety of animal cells in response to viral infection (or various non-viral stimuli) which induce antiviral resistance in homologous cells. In interferon-treated cells, a wide variety of different viruses do not replicate well. It was shown with a majority of the viruses studied that the primary effect of interferon is a general inhibition of viral protein synthesis. In addition to this block it has also been found that with some viruses such as VSV and SV40 the transcription of viral mRNA is decreased in interferon-treated cells. Oncornavirus replication seems to be inhibited by interferon at the level of virus maturation and assembly.

The nature of the molecular mechanism by which interferon induces the antiviral state in the cell has not yet been clarified. Interferon by itself is not an antiviral agent. The antiviral state does not develop in enucleated cells or in cells treated with actinomycin D or cycloheximide. This indicates that the antiviral effect of interferon requires both transcription and translation of the cellular genome and leads to the proposal that there is an interferon-induced antiviral protein (Taylor *Biochem. biophys. Res. Commun.* **14**, 447; 1964). The situation, however, is not that simple; recent results from the laboratories of I. Kerr (MRC, Mill Hill, London), P. Lengyel (Yale University, Connecticut) and M. Revel (Weizmann Institute of Science, Rehovot) with cell-free protein synthesising systems, indicate that interferon treatment induces the synthesis of several translational inhibitors.

The first step in the induction of the antiviral effect is the interaction of interferon with the cellular membrane of a sensitive cell, and it has been observed that the interferon binding involves both cellular gangliosides and glycoproteins (Besancon & Ankel *Nature* **252**, 478; 1974; Vengris *et al. Virology* **72**, 486; 1976; Kohn *et al. Proc. natn. Acad. Sci. U.S.A.* **73**, 3695; 1976). The cellular uptake of interferon is not required for the antiviral effect (Ankel *et al. Proc. natn. Acad. Sci. U.S.A.* **70**, 2360; 1973); the sensitivity to interferon seems to be determined by a receptor located at the plasma membrane. Using antiserum to interferon, which neutralised all free inter-

feron in the medium, Vengris *et al. (Virology* **64**, 410; 1975) demonstrated that for the development of the antiviral state interferon had to interact with the external cellular membrane of the cell producing interferon.

The results obtained by several groups (for example F. Ruddle at Yale University, Connecticut, and F. C. Chany at INSERM, Paris) using mouse-human cell hybrids demonstrated that the sensitivity to human interferon is governed by human chromosome 21. Trisomy 21 cells were markedly more sensitive to human interferon than normal diploid cells or monosomy 21 cells (Tan *et al. Science* **186**, 61; 1974; Chany *et al. Proc. natn. Acad. Sci. U.S.A.* **72**, 3129; 1975). Antibodies to hybrid cells containing human chromosome 21 were found to inhibit the antiviral effect of human interferon in human cells. Revel *et al. (Nature* **260**, 139; 1976) suggested that chromosome 21 codes for the receptor for human interferon on the cell surface.

The species specificity of interferons seems to be also determined at the receptor level. Recent data indicate that in primate-mouse hybrid cells containing only one or a few human chromosomes interferon specificity is due to the interaction with the receptor but the antiviral mechanism induced with both mouse and human interferon is of mouse origin (Chany, *Biomedicine Express* **24**, 148; 1976). This indicates that at least some components of the antiviral effect do not have a requirement for species specificity. Samuel and Joklik (*Virology* **75**, 166; 1976) came to a similar conclusion when they showed that interferon treatment induced a ribosome-associated inhibitor of viral mRNA translation in cell-free systems that could be dissociated from ribosomes and inhibit the translation of viral mRNA in a heterologous cell-free protein synthesising system.

In this issue of *Nature* (page 422) Blalock and Baron from the University of Texas at Galveston present another type of evidence that the interferon-induced antiviral 'machinery' may not be species specific. The authors also suggest that the antiviral compound induced by interferon treatment of the homologous cells can be transferred to the cell of the heterologous species and elicit in it resistance to viral infection. The experiments are based on cocultivation of mouse cells (sensitive to mouse interferon) with interferon-insensitive human cells in the presence of mouse interferon, infection with

VSV or vaccinia virus, and measurement of virus yield. To achieve the effect close contact between the two cell populations was required; the effect was not observed in cultures plated at low cell density. Actinomycin D treatment of the mouse cells blocked both the antiviral effect in the mouse cells and their ability to transfer resistance to the heterologous cells. It seems, therefore, that the transferred compound may be a product of interferon induction rather than interferon itself.

This conclusion, however, is based on experiments done in mass cultures and the challenging viruses replicated both in homologous and heterologous cells. In the future much clearer data would be obtained if the infecting virus could not replicate in the cells homologous to the interferon but only in the cells to which the antiviral compound was transferred. It has been shown previously that the effect of interferon is an all-or-none phenomenon in L cells and in chick embryo cells (Chang *et al. J. gen. Virol.* **20**, 139; 1973; Radke *et al. J. Virol.* **13**, 623; 1974), and thus it should be possible to measure the transfer of viral resistance from the cell in the antiviral state to the adjacent neighbour. Fluorescent antibody or infectious centre techniques could be used to confirm the requirement for cell-cell contact.

One of the remarkable properties of the interferon system is its high biological activity. The specific activity of both human and mouse interferon is estimated to be close to 10^9 units per mg protein (one unit is the amount of interferon which inhibits virus replication by 50%). It is probable that such a system involves mechanisms which amplify the initial response. Both the above described transfer of antiviral resistance and the mobility of the interferon receptors on the cell surface (Lebon *et al. Proc. Soc. exp. Biol. Med.* **149**, 108; 1975) may be amplification factors in the interferon system.

Currently it seems that the action of interferon at the cellular surface resembles in many respects the action of the polypeptide hormones. The major task for the future is to answer the question of how the impulse from the cell membrane is transferred to the nucleus. One possibility which remains to be determined is that the antiviral effect of interferon is mediated through a second message such as cyclic AMP (Weber & Stewart *J. gen. Virol.* **28**, 363; 1975). □

High-energy physics and nuclear structure

from C. J. Batty

A conference on high-energy physics and nuclear structure was held in Zurich on 29 August–2 September and organised by the Swiss Institute for Nuclear Research. This was the seventh in an international series of conferences held every two years. The theme of this conference series is the use of high-energy particles and accelerators to study the properties and interactions of nuclei and the use of low energy techniques and instrumentation to study the fundamental properties and interactions of elementary particles.

OF recent years this field has become increasingly dominated by the three 'pion factories' at LAMPF (Los Alamos), SIN (Zurich) and TRIUMF (Vancouver) and this conference was no exception, with all three accelerators producing a flood of papers on a very wide range of topics but with an

emphasis on proton and pion interactions with nuclei.

Of particular interest on the last day of the conference was a presentation of experiments from all three laboratories on the rare decays of muons. In an introductory talk L. Wolfenstein (Carnegie-Mellon University) briefly reviewed the gauge theories of the weak and electromagnetic interaction which have evolved from the work of S. Weinberg (who also spoke earlier in the meeting on this topic) and A. Salam. Wolfenstein pointed out that recent suggestions of the existence of a third lepton could lead to a coupling between the muon and electron such that decays of the type $\mu \rightarrow e + \gamma$ could occur, although at a very low rate compared with the normal decay $\mu \rightarrow e + \nu_e + \bar{\nu}_\mu$. The question now is, do these rare decays occur?

All three laboratories presented status reports on experiments to measure the relative rate of the decay $\mu \rightarrow e + \gamma$. The work is technically very difficult and much of the discussion was concerned with presenting the many checks and detailed arrangements required to reduce the background to satisfactory levels and to ensure that any events seen which satisfied the

many selection criteria were true rare decays. The TRIUMF team have obtained an upper limit of 3.6×10^{-9} at 90% confidence for the relative rate. In a similar experiment at SIN in which 6.3×10^{11} muons were observed the upper limit obtained was 1.6×10^{-9} again with 90% confidence. In an attempt to reduce these levels even further a group at LAMPF led by H. L. Anderson are using a very high intensity muon beam with a magnetic spectrometer to detect the decay electrons. Running on the experiment has now started and the results are eagerly awaited.

In a related experiment a group at SIN have been looking for interactions of the type $\mu^- + S \rightarrow e^+ + X$ using a sulphur target and a streamer chamber to detect the electrons. Again no true events have been seen and with the very low backgrounds achieved the group are able to set limits of 4×10^{-10} and 1×10^{-9} for reactions leading to electrons or positrons respectively.

However it would be wrong to give the impression that work from the three pion factories entirely dominated the conference. Measurements at Saclay of the scattering of 600 MeV electrons by ^{208}Pb with the cross sec-

It is difficult to test experimentally the effectiveness of r and K selective pressures in the environment. Most of the evidence which has accrued in support of this useful concept has been circumstantial. For example, plant ecotypes of disturbed habitats often produce more seeds per plant and have a lower mean seed weight than their equivalents in stable situations (see *Nature* **262**, 351; 1976) and it is reasonable that one should account for this by reference to the selective pressures imposed upon populations. In a situation where disturbance, or calamity is frequent, the individual with a capacity for rapid and abundant seeding is more likely to have its genes represented in subsequent generations.

One of the clearest demonstrations of this in plants has been the work of Solbrig and Simpson on dandelions (*J. Ecol.* **62**, 473; 1974). In the triploid, apomictic species *Taraxacum officinale*, it has been possible to identify biotypes cytologically which are associated with different grassland conditions. Biotype A is found to predominate in disturbed sites and produce a larger number of smaller seeds than biotype D, which is more common in stable, undisturbed grass-

land. Experimental work has shown that although the two biotypes have similar growth rates in pure cultures, when grown together biotype D is more productive and has a lower mortality (see *Nature* **252**, 191; 1974). In other words, biotype D is more competitive in undisturbed experimental conditions.

Solbrig and Simpson have now (*J. Ecol.* **65**, 427; 1977) developed and extended this experimental approach to the investigation of r and K selection by introducing a disturbance factor

Disturbed environments

from Peter D. Moore

into their experimental conditions. Seven plots of 2 m by 2 m were established and each was divided into four. Of the four subplots, two were planted with a mixture of A and D biotypes of dandelion and the other two with pure populations of each of the biotypes (four plants in each subplot). Screens were erected to prevent seeding from one subplot to another. In two of the seven plots the entire above-ground vegetation was removed (from all four subplots) in the middle of the second and the third growing season. In two more

plots, the above and below ground biomass was removed after tilling the soil (leaving only the residual seed in the soil). The remaining three plots were left undisturbed until the completion of the experiment at the end of the fifth growing season. All dandelions were then dug up, typed cytologically and weighed.

The results after final harvest showed that biotype D dominated the undisturbed plots; 85% of the plants were D type and constituted 91% of the biomass. In the plots where aerial biomass had been removed on two occasions, the situation was reversed and type A was dominant (93% of the plants occupying 93% of the biomass). A similar predominance of type A was found in the plots where all dandelion material (excepting seeds) had been removed. Type A was responsible for 92% of the plants and 97% of the biomass.

It seems therefore that the high competitive ability shown by biotype D in previous experiments indeed depends on no disturbance during the experiment. The balance between the two biotypes in a grassland habitat is evidently controlled by the degree of disturbance experienced. These experimental data therefore fully support the theoretical framework which is currently being assembled around the concept of r and K selection.

Peter D. Moore is a Lecturer in the Department of Plant Sciences, King's College, London.

tions spanning 11 decades have given charge distributions, and hence proton density distributions which significantly disagree with some of the best theoretical nuclear structure calculations. Measurements of electron scattering at high momentum transfer for non-zero spin nuclei give information on magnetic scattering which arises essentially from a single nucleon. Recent measurements of the radii of the orbits of these nucleons are again found to be in significant disagreement with theoretical calculations. It seems to be once again back to the computers for the nuclear structure theorists.

Studies of exotic atoms in which an electron is replaced by a heavier particle such as a muon, pion, kaon, sigma hyperon or antiproton are in progress at several laboratories. A collaboration of groups from the Universities of Birmingham and Surrey and the Rutherford Laboratory using the kaon beam from the Nimrod accelerator (now unhappily due to be closed down next June) reported the first measurements of the effects of the strong nuclear interaction on the line-shapes and energies of X rays from sigma-hyperonic atoms. Much of the discussion in this field however was focused on attempts to observe X rays from \bar{p} -p atoms where the usual electron in the hydrogen atom has been replaced by an antiproton. Teams working at CERN and Brookhaven have so far failed to see any evidence for X rays corresponding to 2p-1S atomic transitions. However a second team composed of physicists from CERN, Daresbury, TRIUMF and the University of Mainz also working at CERN claimed preliminary evidence for the observation of X rays leading to the 2p state. Theoretical calculations also presented at the meeting now suggest that the nuclear interaction in the 2p state may be such as to prevent the observation of 2p-1S transitions.

Although the evidence for X rays from the \bar{p} -p system is still controversial one of the groups at CERN presented some very direct evidence for the observation of high energy γ rays from quasi-stationary bound states of the \bar{p} -p system below threshold. Three narrow γ -ray lines were observed using a very large NaI crystal for detection. The existence of states of this type was predicted several years ago by a group of Russian physicists and their discovery, together with that of narrow resonance in \bar{p} -p interactions at energies just above threshold will give an added impetus to attempts at both CERN and at the Fermi National Accelerator Laboratory in the USA to

produce intense beams of low energy antiprotons for experiments of this type.

From these brief glimpses of just a few of the topics covered at the conference it can be seen that the discussions ranged over a wide variety of subjects. At a time when the two disciplines of high-energy (elementary particle) and nuclear (structure) physics seem to be growing even further apart the conference showed that the two topics have not entirely lost contact and that a very fruitful and productive liaison still exists. \square

The truth about the lower crust

from Peter J. Smith

WHAT is the physical and mineralogical structure of the lower continental crust? Several models have been proposed in the past, ranging from a fairly homogeneous layer of gabbro or basalt (based primarily on geophysical data) to a much more complex zone in which granulitic metamorphic rocks predominate (from geological evidence). Yet, local variations apart, both of these cannot be correct. Ultimately, all geochemical observations must be reconciled and integrated into a single consistent picture, which is what Smithson and Brown (*Earth planet. sci. Lett.* **35**, 134; 1977) have now attempted to do.

The 'simplest and most important conclusion' to be drawn from the new analysis is that the lower crust is certainly not homogeneous. Evidence for heterogeneity has been available for some time in the velocity variations and anomalies revealed by seismic refraction studies. But what really clinches the matter, according to Smithson and Brown, is the existence of numerous seismic reflectors in the lower crust. As they put it themselves: 'With no speculative interpretation at all, these reflections demonstrate the presence of numerous interfaces and a much more complicated lower crustal structure than has previously been supposed.'

Indeed, things are more complicated than even the mere presence of reflectors would suggest, for individual reflectors usually lack continuity. Moreover, the lower crust must on average be 'distinctly less mafic (and less dense) than gabbro', partly

because most seismic velocities found there correspond to granulitic facies rocks from granitic to intermediate composition and partly because if the most mafic rock type to be expected there in general is gabbro, more felsic rocks must also be present in abundance to provide the contrasts giving rise to the reflections.

What Smithson and Brown concluded from all this and more (for example, from direct observation of lower crustal sections now exposed) is that the lower crust can only be a complex series of metamorphic rocks interspersed with igneous bodies. Specifically, it probably comprises such rock types as granite gneiss, syenite gneiss, anorthosite, pyroxene granulite and amphibolite, all deformed, interlayered with both sharp and gradational contacts, and intruded by granite and gabbro. In such a predominantly metamorphic environment, isoclinal folding, abrupt changes in dip, distortion of layers, changes in layer thickness and igneous intrusion are only to be expected, offering an obvious explanation for the discontinuous reflectors observed.

The age of innocence is over as far as the lower continental crust is concerned. As a few people have consistently maintained, the geophysical simplicity has always been merely an illusion based on insufficient data. Not that geophysical data will ever be sufficient. For as Smithson and Brown point out, 'if the lower crust is metamorphic, not even high-resolution seismic reflection studies will ever reveal the detailed structure. Complex fold patterns... are unlikely to be resolved by any geophysical method.' \square

The nucleolus at Salamanca

from E. G. Jordan and U. E. Loening

The Fifth European Nucleolar Workshop of the European Cell Biology Organisation (ECBO) was held at the University of Salamanca on 27 June-1 July 1977, and was organised by Professor Giménez-Martín and others from the Consejo Superior de Investigaciones Científicas (CSIC), Madrid.

W. BERNHARD (Institute for Cancer Research, Villejuif) opened the workshop with the hope that the many specialities represented might be integrated, even if it was too early to speak of a synthesis, through a mutual respect and understanding between scientists.

The nucleolar rRNA genes provide an excellent system for studying transcription and gene organisation. The 'spreading technique' for visualising transcription in the electron microscope was first developed using nucleolar genes by Miller and Beatty. It has now been combined with autoradiography by N. Angelier *et al.* (Centre de Recherche, Ivry Seine) and S. Fakan *et al.* (Cancer Research Institute, Lausanne) to study transcription in nucleolar genes from amphibia and non-nucleolar genes from mammalian cells respectively. Autoradiographs of the typical nucleolar 'Christmas tree' transcriptional unit gave two surprising quantitative results. First, genes which were morphologically identical nevertheless showed different incorporation rates, indicating separate, single cistron control of the rate of transcription. Second, the latter part of the 'Christmas tree' covering the last third or so of the transcribed area showed no increase in the specific activity of the RNA. This may suggest that processing, the trimming of the transcript by nucleases, begins before termination.

One outstanding question is whether there are different sets of ribosomal genes. U. Scheer (Cancer Research Centre, Heidelberg) presented evidence for several size classes of transcription unit within the same organism although the apparent length of consecutive units on the same DNA axis seemed very uniform. M. Buongiorno-Nardelli (Embryology Institute, Rome) showed, in *Drosophila*, that the ribosomal genes of the same size class occur adjacent to each other in blocks and only selected size classes are amplified. Not only may the spacers and transcription units be different in length, but further confirmation that the rRNA precursor may be heterogeneous was again forthcoming. Scheer confirmed that the molecular weight of the pre-rRNA did not always agree with the transcript length and was sometimes heterogeneous. Supporting Scheer's electron micrographs D. Rungger and M. Crippa (University of Geneva) provided evidence that it is possible to detect RNA which hybridises to cloned ribosomal spacer DNA and that longer transcripts than the 40S pre-rRNA in *Xenopus* can be detected when processing is inhibited by fluorouridine. This suggests that transcription sometimes runs into the spacer.

A lively round-table discussion tried to put these and other results together: it is still not possible to define the primary transcript exactly since the pre-

rRNA may already be partially processed; no triphosphates have been found at the 5' start of the precursor; there may be some variability or multiplicity of initiation sites and read-through into the spacer, and perhaps a sliding or non-transcriptional movement or relocation of the polymerase carrying the RNP fibril. The mechanism and control of transcription of the ribosomal genes is clearly far from being understood despite the large amount of established data. The failure to find initiation *in vitro* with isolated nucleoli does not at present clarify anything.

However, as on every previous occasion, possible candidates for enzymes which process the precursor were described. M. Muramatsu (Tokyo University) had one; I. Grummt (Max-Planck-Institute, Munich) in collaboration with R. Crouch and S. Hall (National Institutes of Health, Bethesda) described a purified enzyme from the nucleolus which cleaves double-stranded RNA and converts the 45S precursor into distinct cleavage products; it is inactive under the conditions usually used for *in vitro* transcription by nucleoli. Perhaps this time a real processing enzyme has been identified. The spreading technique also provides evidence for the absence of nucleosomes in the nucleolar transcription complexes, which have the same length as measured on purified DNA (Scheer). This can be reconciled with the biochemical evidence for the presence of histones in the transcription complex by the idea that the nucleosome is a dynamic structure (reviewed by T. Tsanev (Bulgarian Academy of Sciences)) whose components may be rearranged in certain conditions. This would allow the conclusion that all the histones are present and arranged in units which can readily associate to form nucleosomes but which are sensitive to detergent and may only appear as a 3-nm fibril in spread preparations.

A clue to the way histones and nucleosomes might regulate transcription was presented by H. Busch (Baylor College of Medicine, Texas). By comparing the protein patterns from chromatin from active and inactive nucleoli he has discovered four proteins which markedly decreased in active chromatin. One of these proved to be a branched molecule containing a complete H2A sequence linked to the protein ubiquitin. One-fifth of the nuclear H2A could be accounted for in such molecules. He postulated that such a molecule in this proportion might easily have a key role in transcriptional regulation through the linking of nucleosomes in the stabilisation of the supercoils in condensed chromatin.

Various reports showed that both

HnRNA and nucleolar RNA synthesis is located at a cytological boundary. For HnRNA this is between dense and diffuse chromatin; for rRNA it is at the surface of the nucleolus organising region within the nucleolus.

Several speakers addressed the problem of how pre-messenger RNA is transported to the cytoplasm. It appears that it is wrapped in a wide variety of proteins, transported to the cytoplasm through the nuclear pore and there stored as protein-bound RNA or used immediately on polysomes. S. Penman (Massachusetts Institute of Technology) described a cytoskeleton (See *Cell* 10, 67; 1977) on which all cellular RNP is apparently translocated within the cell. Penman believes that this cytoskeleton provides a morphological explanation for the rapid interference with processing and translocation when transcription is inhibited and also accounts for the fact that RNA is never 'free' in the cell.

Support for the idea of such a cytoskeleton was provided by U. Lönn (Karolinska Institute, Stockholm) who reported microdissection experiments on the cytoplasm of polytene cells

A hundred years ago

SOME of our readers may like to know that, as might have been expected, the three rhinoceroses now exhibited in the Alexandra Park are specimens of the African Black Rhinoceros (*Rhinoceros bicornis*). This species is extremely uncommon in menageries, and we have heard of no other in this country except the fine adult male now living in the Zoological Society's Gardens in Regent's Park.

It is perhaps a fortunate thing that our politicians, like the Chancellor of the Exchequer and Mr. John Bright, are beginning to concern themselves in their public addresses with science as well as art. With reference to Mr. Bright's recent address, as the *Times* remarks, if his hearers complain that they have not been told much about either science or art, we can only say that we agree with them, and that we deplore our common loss. In the coming time it is to be hoped that public speakers, like Mr. Bright, will know better what science really is than they seem to do now.

from *Nature*, 14, 27 September; 1876.

E. G. Jordan is in the Department of Biology at Queen Elizabeth College, London and U. E. Loening is in the Department of Zoology, University of Edinburgh.

which showed a gradient of ribosomes from nuclear envelope to plasma membrane, with the oldest ribosomes furthest from the nuclear membrane. The discovery of a very specific 28S rRNA nicking enzyme in erythrocyte cell membranes (M. Herzberg, Bar-Ilan University, Israel) fits with the idea that the lifetime of a ribosome is the time it takes to traverse this gradient.

The old idea of a link between the transport of messenger and ribosomal RNA which implies a role for the nucleolus in all RNA transport was supported by a report from S. Ghosh (Cancer Research Centre, Heidelberg) who showed that RNA transport was much lower in the absence of a nucleolus in artificially produced multi-nucleate cells.

It might be that the dogma that RNA polymerase A is confined to the nucleolus and polymerase B to the nucleoplasm does not hold any more. Penman questioned the former and a report from M. Laval (Cell Pathology Laboratory, Paris) using high resolution autoradiography, found evidence for polymerase B activity within the nucleolus. Such observations and a possible function in the transport of RNA make us cautious in limiting the role of the nucleolus to ribosome

manufacture.

Several speakers provided evidence that the so-called 'fibrillar centres' in animal cells and the lacunae of nucleoli in plant cells are in fact nucleolar organising regions. These reports precipitated a special session to discuss nucleolar nomenclature and agreement was reached that evidence for the presence of DNA in the fibrils of the pale staining regions, especially that from cytochemistry and autoradiography, and the presence of a synaptonemal complex at meiosis, justified abandoning the various vague and misleading terms 'fibrillar centre' 'pars amorpha' or 'lacunae' in favour of the nucleolar organising region. Bernhard observed that this represented an important advance since the last nucleolar workshop in 1975 in our progress towards an understanding of the nucleolus. It clarifies much of the earlier work and suggests a unifying concept for the interpretation of nucleolar ultrastructure.

Certainly this meeting will be remembered for the atmosphere of quiet scholarship in the midst of this beautiful old University city, and for considerable success in correlating structural with biochemical findings on the nucleolus and nucleus.

were reported in its diagnosis at an early stage. The test consists of the examination of oesophageal cell scrapings which are collected by a single-lumen tube or a double-lumen tube with an abrasive balloon (both of Chinese improved design). These on-the-spot techniques have made possible mass screening of patients, and the probability of detecting carcinoma in its early stages is now better than 90%. Its incidence in various areas of central and southern China has been correlated with possible carcinogenic factors such as local climatic conditions, hydrogeology, soil types and trace elements, diet and particular life-style. In some areas, which now serve as bases for experiments, the populace are voluntarily attempting to reduce their intake of nitrosamines and their precursors (suspected of contributing also to cancers of the bladder, kidney, liver, stomach and nasal sinuses), to minimise fungal contamination of food and to apply ammonium molybdate as fertiliser (nitrates and nitrites in food are suspected of being precursors to the nitrosamines), and the effects of such measures are being monitored. The principle 'put prevention first', it was emphasised, was paramount in the running of the Chinese health care system.

Another main topic of discussion was liver cancer. The method for its detection most widely used in China is the serum α -fetoprotein assay, which requires only a drop of blood from the individual's ear or finger. Great success has been achieved in its early detection; specimens of it have been obtained which have not grown larger than 0.5 mm. In areas where it is common, efforts have been made to prevent mould contamination of food and improve drinking water, and to ensure early treatment of hepatitis by medical education. Other topics covered included the viral aetiology of nasopharyngeal carcinoma, to which southern Chinese people are particularly prone. Some medical workers reported that they have prepared several lymphoblastoid cell lines and found Epstein-Barr virus, and have successfully established an epithelioid cell line of the carcinoma.

Part of the conference was also devoted to cancer therapy and pharmacology. Over the past few years the Chinese claim many new anti-tumour drugs have been discovered. With the help of traditional medical knowledge some effective anti-cancer drugs, especially N-formylsarcosine and cephalotaxine ester, an alkaloid extracted from the plant *Cephalotaxis fortunei*, have been identified and their effectiveness is now being assessed in clinical practice. □

Cancer conference in China

from T. B. Tang

A NATIONAL retrospective survey of cancer deaths is being compiled in China, on a scale which is probably unique hitherto. The investigation began in 1971 and was started first as a pilot project in Lian-axian in the north of Honan Province. That county is inhabited by some 110,000 people and has a high incidence of oesophageal cancer. The survey established that over a 30-year period the toll taken by the disease had been constant each year, at an annual average of between 1 and 1.5 per thousand. This is despite significant emigration and immigration into the district and improvement in living conditions since 1949, suggesting that the main contributory factors to this cancer are environmental.

The work has been subsequently expanded to cover the 50 million people living in Peking and three provinces of North China. Then, on the basis of experience from this extended survey, the incidence of a number of impor-

tant cancers was investigated nationally by the Academia Sinica. This programme involved eight of the Academia's research institutes and the 1.8 million barefoot doctors in the countryside. Up to now 500 million people in 16 provinces, municipalities or autonomous regions have been covered, and the research is still going on.

It is therefore interesting to note that, at the beginning of July, a national conference was held in Peking on the epidemiology of malignant tumours (*Hsinhua News Agency*, July 26; *Tai-kung-pao*, September 4, special report). Some 300 workers attended, including delegates from regional cancer research institutes, rural barefoot doctors, and practitioners of both traditional Chinese medicine and Western medicine. Experience was exchanged and summed up, theses were put forward and debated on, and before the meeting concluded a work programme for 1977/80 was mapped out.

Carcinoma of the oesophagus remained one of the main concerns at the conference. Significant advances

review article

Recent developments in phase transitions and critical phenomena

David R. Nelson*

Universal dimensionless numbers characterise singularities at the critical point in magnets, binary mixtures and alloys, superfluids, and in a variety of other systems. A desire to understand these numbers has stimulated a significant breakthrough in the analysis of statistical mechanical partition sums. Critical phenomena can now be understood in terms of universality, Hamiltonian flows, and renormalisation group recursion relations.

PHASE changes of matter in thermodynamic equilibrium are often accompanied by sharp discontinuities in quantities such as the magnetisation in a ferromagnet, the density in a liquid-vapour system, or the concentration in a binary mixture. Usually, these phase transitions can be made continuous by adjusting some external parameter such as the temperature. The point at which the discontinuity vanishes is called a critical point. At temperatures above the critical point, the spontaneous magnetisation of a ferromagnet is zero, the liquid and vapour phases of a fluid become indistinguishable, and the chemical species present in a binary fluid mixture are completely miscible. One usually associates the discontinuities below the critical temperature with some sort of broken symmetry¹⁻³.

Although critical points were discovered in the nineteenth century, they have been the focus of particularly intense scientific investigation during the past few decades¹⁻³. A rather precise characterisation of critical point singularities by experiments⁴ and perturbation techniques such as high temperature series expansions⁵ was followed by a detailed theory due to Wilson⁶. In this review, I shall describe Wilson's renormalisation group approach to critical phenomena, and illustrate its utility with examples chosen from the recent literature.

The spontaneous magnetisation and susceptibility of a ferromagnet are plotted schematically in Fig. 1. Below the Curie temperature, a substance such as iron or nickel will support a spontaneous magnetisation $M_0(T)$, which accounts for the well known magnetic properties of these substances. As the temperature is raised, however, the magnetisation drops to zero at T_c as shown in the figure. The magnetic susceptibility in zero field, $\chi_0(T)$, which is a measure of the response of the magnetisation to a small magnetic field, actually diverges to infinity as one approaches the Curie temperature from above or below.

The extraordinary thing about the anomalies shown in Fig. 1 is that they seem to be universal. That is, a wide variety of ferromagnets displays spontaneous magnetisations which tend to zero and susceptibilities which apparently diverge in precisely the same way. Despite differing chemical compositions, lattice structures, and Curie temperatures, one finds that $M_0(T)$ behaves as

$$M_0(T) \sim |T - T_c|^\beta \quad (1)$$

near T_c , while $\chi_0(T)$ diverges according to

$$\chi_0(T) \sim |T - T_c|^{-\gamma} \quad (2)$$

where the critical exponents β and γ are essentially the same for all magnets. A second curious fact is that the universal numbers β and γ are not simply one-half or unity, although most simple theories lead inevitably to these values¹⁻³. In fact, experiments⁴ and evidence from high-temperature series expansions⁵ suggest that β and γ lie in the ranges,

$$0.31 \lesssim \beta \lesssim 0.38 \quad 1.25 \lesssim \gamma \lesssim 1.38 \quad (3)$$

in most substances. Although equation (3) indicates some variation in the observed values of β and γ , it now seems that magnets with the same symmetry should have precisely the same exponents: that is, if we imagine that a magnetic crystal is described by a lattice of classical spin vectors (see Fig. 2a), there is a weak dependence of critical exponents on the number of spin components n which actively participates in the phase transition. The number of such spin components is related to the symmetry group of the crystal.

The universality of critical phenomena is not limited to ferromagnetism. Analogous quantities to the magnetisation and

Fig. 1 The magnetisation $M_0(T)$ and zero field susceptibility $\chi_0(T)$ of a ferromagnet. The magnetisation goes to zero at the Curie temperature T_c , while $\chi_0(T)$ diverges as this temperature is approached from above or below.

*Lyman Laboratory of Physics, Harvard University, Cambridge, Massachusetts 02138

Fig. 2 Kadanoff block scheme. Dashed lines enclose groups of spins on lattice (a), which is at temperature T . Out of each block, we construct a collective spin variable by integrating over the internal degrees of freedom. The new spin degrees of freedom populate a lattice (b) with twice the old lattice spacing, and interact as if they were at temperature T' .

susceptibility exhibit singularities at the critical point of liquid-gas systems, binary mixtures, and alloys, at the λ -transition in superfluid helium, and at the Néel temperature in antiferromagnets¹⁻³. Exponents such as β and γ which characterise the anomalous behaviour are very close to the numbers found for ferromagnets. A variety of other exponents can be defined for systems near a critical point, and they, too, seem to be universal.

The behaviour of a liquid-gas system near its critical point is particularly striking. The fluid suddenly becomes milky and opaque, and scatters laser light intensely in the forward direction. It seems clear that some sort of cooperative phenomenon is taking place, and that the particles of fluid are strongly correlated over distances comparable with the wavelength of the laser light. The correlation length $\xi(T)$ of the fluid, which is a measure of the cooperativity, is expected to diverge strongly at T_c .

$$\xi(T) \sim |T - T_c|^{-\nu} \quad (4)$$

The exponent ν is in the range

Fig. 3 Approximate recursion relation for $n = 1$ or Ising spins, with a fixed point at $T^* = T_c = 2.98$. The 'ladder' construction shows successive temperatures produced by repeated iterations of the transformation. The slope of the function $T'(T)$ through its fixed point is related to the critical exponent ν .

$$0.64 \leq \nu \leq 0.70 \quad (5)$$

in most substances.

Where do the universal exponents β , γ , and ν come from? What is their precise numerical value? Can we account for slight variations, if any, in β , γ , and ν from system to system? A desire to answer these puzzling questions culminated in a major breakthrough in 1971. Wilson's renormalisation group theory of critical phenomena⁶. Building on work by Kadanoff⁷, Wilson showed why the exponents were universal and how to calculate them. In doing so, he placed at the disposal of condensed matter physicists a powerful mathematical tool, the renormalisation group.

Kadanoff blocks and lattice renormalisations

If critical exponents are indeed universal, one might hope to understand them using only a very simple model of magnetism. Consider for concreteness a d -dimensional hypercubic lattice populated with fixed length, classical spin vectors S_i (see Fig. 2). To each configuration $\{S_i\}$ of spins we assign an energy,

$$H[\{S_i\}] = -J \sum_{\langle i,j \rangle} S_i \cdot S_j \quad (6)$$

where i and j label the sites of the lattice, and the sum is restricted to nearest-neighbour pairs of spins. Each spin has n components, where n can be different from d , the dimensionality of space. According to the rules of statistical mechanics, the macroscopic properties of such a system follow from a calculation of the partition function,

$$Z = \text{Tr}_{\{S_i\}} \exp(-\beta H[\{S_i\}]) \quad (7a)$$

$$\equiv \text{Tr}_{\{S_i\}} \exp\left(-\frac{1}{T} \sum_{\langle i,j \rangle} S_i \cdot S_j\right) \quad (7b)$$

In passing from (7a) to (7b), we have combined β (not to be confused with a critical exponent!) and the coupling constant J into a dimensionless 'temperature', $T \equiv 1/\beta J$. The trace operation (Tr) means an integration over all spin configurations $\{S_i\}$ consistent with the fixed length requirement, namely

$$|S_i| = 1, \text{ all } i \quad (8)$$

The partition sum (7) can be computed exactly in one dimension for all values of n (ref. 8) but does not exhibit a finite temperature phase transition. Onsager obtained the partition function in two dimensions⁹ for the special case of the Ising model, or $n = 1$. Onsager's work, which remains today a true mathematical *tour de force*, eventually led to the exponent predictions¹⁻³

$$\beta = \frac{1}{8}, \quad \gamma = \frac{7}{4}, \quad \nu = 1 \quad (9)$$

An analytical evaluation of (7) for other values of n and d seems to be a hopeless task.

Rather than attempting to evaluate (7) exactly, we can, in fact, make progress by merely thinning out the spin degrees of freedom slightly. To do this, we follow the original suggestion of Kadanoff⁷ and group the spins on the original lattice (which is at temperature T) into blocks as shown in Fig. 2. With some ingenuity, it turns out to be possible to integrate approximately over the internal degrees of freedom within each block. We are then left with a new statistical mechanical problem with twice the lattice spacing. Provided the interactions between spins in the new lattice are of the same form as in the old, couplings in the new lattice can be characterised simply by a new temperature T' .

This sort of program was first carried successfully for Ising ($n = 1$) spins on a triangular lattice by Niemeyer and van Leeuwen¹⁰. A very primitive version of their transformation gives a relationship between the new and old temperatures, namely¹⁰

$$T' = \frac{1}{2} T (e^{3/T} + 3e^{-1/T})^2 / (e^{3/T} + e^{-1/T})^2 \quad (10)$$

Equation (10) is depicted graphically in Fig. 3, together with a

'ladder' construction which shows how the temperature changes with repeated iterations of the transformation. The recursion formula (10) has a fixed point at $T^* \approx 2.98$, and it seems natural to identify this isolated point with the Curie temperature T_c of the spin system.

We can see the utility of this procedure of 'thinning out' spins as follows: even an approximate calculation of partition function (7) is difficult near T_c because of the large correlation length $\xi(T)$ in this region. Note from Fig. 3, however, that the renormalisation transformation increase temperatures which, initially, are slightly above T_c . By repeatedly applying the transformation (10), we can relate a difficult calculation near T_c to a more tractable high temperature problem. A very accurate calculation of the partition sum (7) is possible at high temperatures by expanding in powers of $1/T$. No information about Z is lost during the thinning out procedure, because there is a very precise relationship between the partition function calculated at temperature T , and the corresponding quantity calculated at temperature T' (refs 6 and 10–12). In a similar fashion, we see that the transformation (10) decreases temperatures initially slightly below T_c , and eventually produces a more manageable (low temperature) problem.

As emphasised by Wilson¹⁴, the physics behind a renormalisation transformation is in the reduction of the correlation length. If the lattice spacing is changed by a factor b by the thinning out process, it follows the correlation length transforms according to¹⁴

$$\xi(T') = \xi(T)/b \quad (11)$$

For the square lattice spin system shown in Fig. 2, $b = 2$, while for the triangular lattice of Niemeyer and van Leeuwen (it turns out that)¹⁰ $b = \sqrt{3}$. Equation (11) can be used in conjunction with (10) to produce a critical exponent. Near the fixed point $T^* = T_c = 2.98$, equation (10) can be written in the approximate form,

$$T' - T_c = b^{0.89} (T - T_c) \quad (12)$$

which when combined with (11) gives a functional equation for $\xi(T - T_c)$,

$$\xi(T - T_c) = b \xi[b^{0.89} (T - T_c)] \quad (13)$$

It is easy to check that the solution of this functional equation is $\xi(T) \sim |T - T_c|^{-\nu}$ with $\nu \approx 1.12$, which is not too different from the exact result $\nu = 1.0$.

In more sophisticated calculations^{10,15–18}, it is not possible to describe a renormalisation transformation in terms of a single coupling constant. More complicated couplings such as next-nearest-neighbour and multispin interactions are generated after one iteration. When these extra couplings are taken into account^{10,15–18}, they not only produce more accurate estimates of critical exponents, but also provide a qualitative explanation of universality: if several couplings are included in the calculation, the renormalisation transformation can be viewed as a mapping of one Hamiltonian to another in a multidimensional coupling-constant space. As T is adjusted towards T_c , it turns out that any initial set of couplings 'flows' toward a unique fixed point under repeated applications of the transformation. Just as in the one-interaction-constant example, critical exponents are related to eigenvalues of the transformation about this fixed point. We are led to the conclusion that the exponents are independent of the precise values of the initial couplings, and depend instead on the 'universal' properties of the fixed point.

Calculations by the Kadanoff block method for Ising spins have now become quite refined. Niemeyer and Van Leeuwen¹⁰ presented a series of cluster approximations to an exact transformation which seems to converge to the exact results of Onsager. Wilson¹⁵ carried out renormalisations on a square lattice keeping track of 217 different interaction constants, and obtained critical exponents accurate to better than 1%. Kadanoff has proposed a variational principle^{17,18} which, when coupled with a simple block

spin transformation, gives exponents accurate to 0.1% in two dimensions, and results competitive with high temperature series expansions in three dimensions!

Despite some initial success, this field is still in its infancy. The principal achievement of the block spin analysis so far (beyond providing an intuitive understanding of universality) has been to reproduce the results of Onsager and high temperature series expansions. Nevertheless, lattice renormalisation groups may eventually become a powerful computational tool, similar to various methods used to evaluate integrals numerically in ordinary calculus. The partition sum (7) can be viewed as a complicated functional integral which until now could only be computed in a few fortuitous cases. Renormalisation theory suggests that such sums can be evaluated routinely and very accurately at any temperature, without relying on a mathematical *tour de force* such as Onsager's solution⁹ of the two-dimensional Ising model.

Continuation in dimensionality

Wilson has characterised developments in the theory of critical phenomena as a "search for analyticity". The idea is to find a mathematical framework in which critical point singularities are described by smooth, analytic functions. Landau¹⁹ proposed that critical phenomena could be understood in terms of an analytic expansion of the free energy in powers of a local magnetisation variable. Although Landau's theory has led to a qualitative understanding of a wide variety of critical points, the exponent predictions disagree with experiments^{1–3}.

The proposal that critical points can be understood in terms of analytical recursion relations⁶ seems to be the correct modification of Landau's theory. The method of construction ('thinning out' degrees in freedom) virtually guarantees that the recursion relations will be analytic at finite temperatures. Wegner¹⁹ has shown that a wide variety of critical point singularities follow from the analyticity of recursion relations about a fixed point.

Perhaps the most useful analyticity property of recursion relations is that they are remarkably easy to continue in dimensionality. The original continuation of Wilson and Fisher into $4-\epsilon$ dimensions (Landau's theory turns out to be correct above $d = 4$) led to quantitatively accurate estimates of exponents in three dimensions, and to a detailed understanding of a wide variety of complicated critical point phenomena. The formulas for β and γ as a function of n and d ($d < 4$) are^{21,22}

$$\beta = \frac{1}{2} - \frac{3}{2(n+8)}(4-d) + \frac{(n+2)(2n+1)}{2(n+8)^3}(4-d)^2 + \dots \quad (14a)$$

$$\gamma = 1 + \frac{n+2}{2(n+8)}(4-d) + \frac{(n+2)(n^2+22n+52)}{4(n+8)^3}(4-d)^2 + \dots \quad (14b)$$

Although expansions like these in $\epsilon = 4-d$ (and, to a lesser degree, expansions in $1/n$)^{23–25} probably represent the most powerful and versatile application of Wilson's theory, this work has been extensively reviewed elsewhere^{14,26–28}. We shall turn instead to more recent investigations of critical points in $2+\epsilon$ dimensions.

Critical phenomena in $(2+\epsilon)$ dimensions

To a first approximation, the action of a renormalisation group on a Hamiltonian can be compared with the motion of a ball rolling down a hill⁶. One assumes that the differential change in temperature $dT \equiv T' - T$ associated with a block spin transformation that changes the lattice spacing by a factor $d/l \equiv db/b$ is described by a potential function $V(T)$ (ref. 6)

$$\frac{dT(l)}{dl} = -\frac{dV(T(l))}{dT(l)} \quad (15)$$

Here, d/l is an infinitesimal change in the logarithm of the Kadanoff block size, and $T = T(l)$ is the effective temperature produced by

Fig. 4 Potential function $V(T)$ for fixed length spins in $2+\epsilon$ dimensions, with ϵ small and $n \geq 3$. Hamiltonians initially to the right of T_c 'roll' toward higher temperatures, while systems with temperatures less than T_c roll toward a zero temperature fixed point.

blocks of size $b = e^l$. Although a differential change in the block size is hard to visualise, it turns out to be fairly easy to effect this transformation mathematically.

Recent studies of the fixed length spin Hamiltonian (7) near two dimensions²⁹⁻³⁴ provide a particularly simple realisation of these ideas. The potential $V(T)$ has now been calculated by using a low-temperature spin-wave theory, with the result^{29,31}

$$V(T) = \frac{1}{2}(d-2)T^2 - \frac{n-2}{6\pi}T^3 + \dots \quad (16)$$

As shown in Fig. 4, Hamiltonians at temperatures initially to the right of the crest in this potential roll toward high temperatures, while Hamiltonians at lower temperatures roll toward the minimum at $T = 0$. There is no oscillatory motion about this minimum because the 'equation of motion' (15) contains only one derivative in the time-like parameter, l .

This is precisely the behaviour we found using the discrete recursion formula (10), and it is natural to associate the crest of the potential hill with the critical temperature,

$$T_c = 2\pi(d-2)/(n-2) \quad (17)$$

In contrast to the $n = 1$ or Ising model, T_c tends to zero as d approaches two from above for $n \geq 3$. Linearisation of the equation (15) about the maximum in the potential leads to the correlation length exponent prediction²⁹⁻³¹

$$\nu = \frac{1}{(d-2)}[1 + O(d-2)] \quad (18)$$

Higher order corrections to this result are determined in ref. 31.

Note that for the interesting case of an XY model ($n = 2$) in precisely two dimensions, the potential (16) is perfectly flat. This result (which holds to all orders in T) suggests that such a system would exhibit a line of critical points with continuously variable critical exponents³⁵⁻³⁶. Work by Berezinskii³⁷ and by Kosterlitz and Thouless^{38,39} gives convincing evidence that this line actually ends at some finite temperature. Renormalisation group flow patterns for the XY model obtained using a more sophisticated theory by Kosterlitz³⁹ and later by José *et al.*⁴⁰ are plotted in Fig. 5, which shows the motion of the temperature coupling $T(l)$ together with the motion of a new parameter $y(l)$, which gives the probability of a vortex pair excitation in the system. These flows suggest that vortices become unimportant at low temperatures, so that spin-wave theory (which neglects vortices) should be qualitatively correct in region I. The instability in the flows in regions II and III, however, suggests a finite temperature transition into a phase not describable by spin-wave theory. It is possible that this bizarre phase transition may actually be observable in superfluid ⁴He films.

Concluding remarks

We have seen that the renormalisation group is a rather powerful and sophisticated tool for understanding the behaviour of matter near a critical point. Much of the progress in this area resulted from a rather fertile interaction of statistical mechanics with quantum field theory, where the renormalisation group was first developed⁴¹. Renormalisation groups constructed for problems in statistical mechanics may eventually be of some use in understanding certain lattice quantum field theories⁴².

Modern renormalisation theory may also be useful in other areas of condensed matter physics. Anderson⁴³ and Wilson¹⁵ have applied renormalisation group ideas to the Kondo problem, while Licciardello and Thouless⁴⁴ and Wegner⁴⁵ have used these techniques to study localisation in metals. Equilibrium time-dependent critical phenomena have been successfully treated⁴⁶ using Wilson's ideas, and there is now some effort to extend these techniques to non-equilibrium problems. One might hope that they would be of some utility in understanding, for example, properties of turbulent fluids at high Reynold's number.

Much of my understanding of static critical phenomena is the result of stimulating interactions with Michael Fisher, Kenneth Wilson, and Leo Kadanoff.

This research was supported in part by the National Science Foundation.

Fig. 5 Hamiltonian flows for the two-dimensional XY model. The flowlines show the motion of the coupling constants T and y under repeated iterations of a renormalisation group transformation. The parameter y measures the probability of exciting a vortex pair in the system. The flowlines are both attracted and repelled by a line of fixed points at $y = 0$. Two separating trajectories divide the plane of possible Hamiltonians into three distinct regions. Vortices are unimportant to the critical properties in region I, but become increasingly important in regions II and III.

The Mediterranean Sea became isolated from the world ocean in the late Miocene and underwent a 'crisis of salinity' during which vast deposits of evaporites were laid down in pre-existing depressions. The final connection with the Atlantic is believed now to have been the Betic Strait entering into the Mediterranean from Andalusia, Spain. Although the closing of this connection, known as the Iberian Portal, is related to large-scale plate movements which brought Africa into direct contact with southern Europe, its final severing may have resulted from glacial-eustatic lowering of the global ocean. Further stratigraphic resolution of late Miocene sea-level and ice-volume changes is sought to verify the eustatic-fall hypothesis.

RECENT research, particularly that of specialists contributing reports on the DSDP legs 13 (refs 1, 2) and 42A (ref. 3) has revealed the existence of 1.5-2 km of evaporites throughout the deep Mediterranean basins and has strongly supported Ruggieri's⁴ suggestion that a 'crisis of salinity' overwhelmed the faunas of the ancient Tethys Sea in latest Miocene (Messinian) time some 6.5-5 Myr ago (Fig. 1).

The salinity crisis occurred after the western Tethys lost its last connection with the Atlantic about 6.2 Myr BP (ref. 5), its connection with the Indo-Pacific having been severed at about the end of the Early Miocene⁶ some 10 Myr earlier. The Iberian Portal, as the hypothetical last connection with the Atlantic is often known, must have existed somewhere between the Iberian Meseta and the Moroccan Meseta and could have been any one of the former Betic, Gibraltar, or Rif straits, although Benson⁷ now believes that its connection to the Atlantic lay across Andalusia and was therefore the northernmost of the three passages. Isolation of the ancient Mediterranean from the world ocean resulted in the precipitation of more than 10⁶ km³ of gypsum, halite and other salts from a volume of seawater estimated to be equivalent to thirty times that contained in the present Mediterranean basins⁸.

The connection between the Atlantic and the Mediterranean may have been broken by plate movements bringing Africa into direct contact with southern Europe⁹ or by uplift of the sea floor associated with the Alpine Orogeny (doubtless two aspects of the same basic process). It is possible, however, that the final separation of the Mediterranean from the Atlantic could have been brought about by a fall in the level of the world ocean¹⁰ or by a combination of local uplift of the Iberian Portal and global eustatic

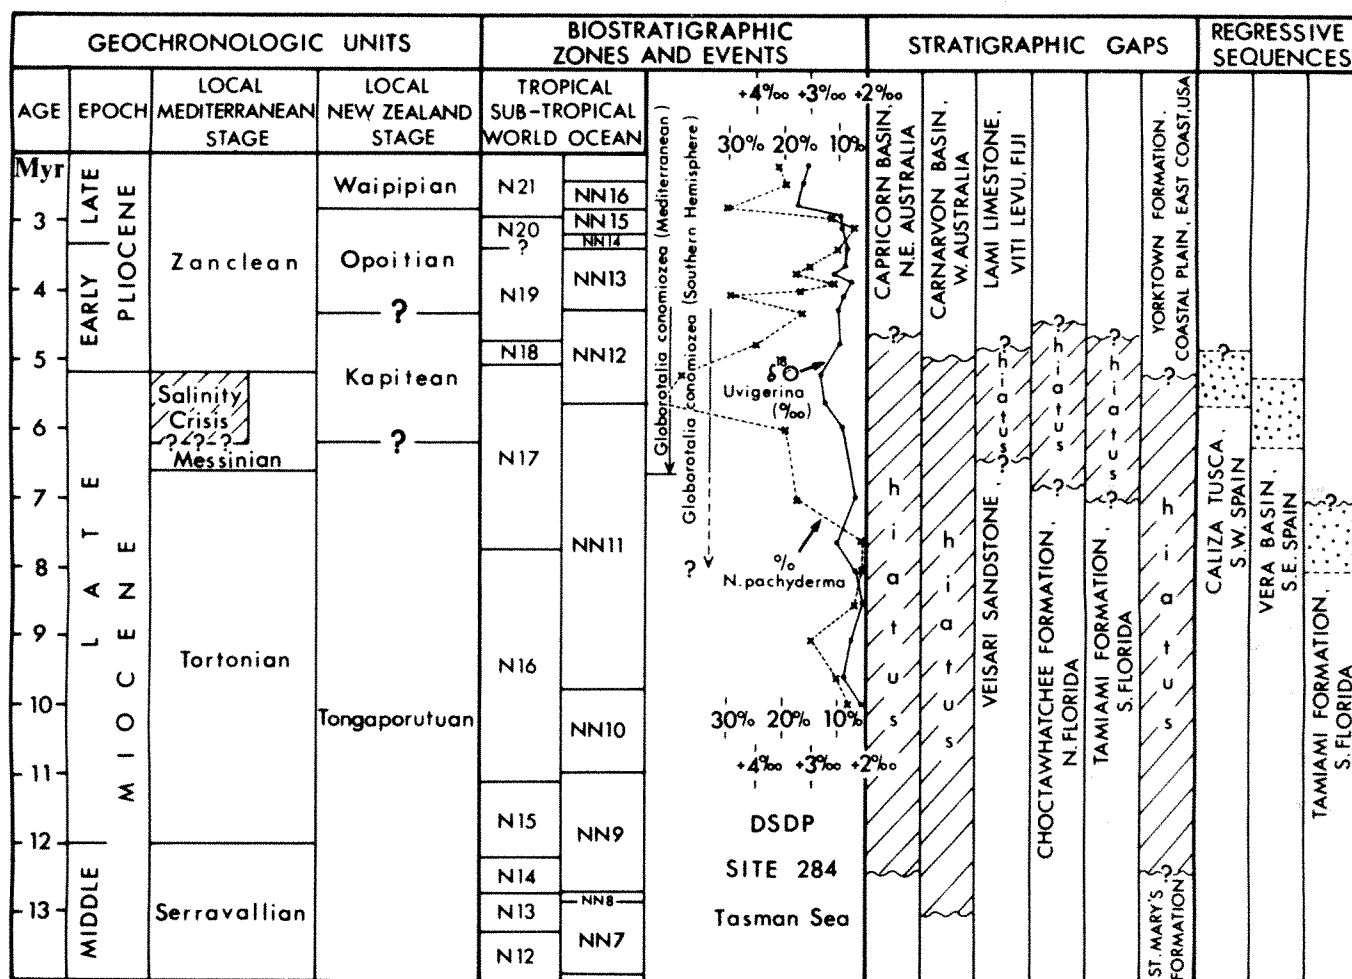

Fig. 1 The Miocene/Pliocene stratigraphic interval with position of stage boundaries and the Mediterranean salinity crisis relative to world ocean biostratigraphic zones, various climatic events, erosional gaps in shallow-water formations and regressive sequences discussed in the text.

oscillations. We examine here the evidence for eustatic change without implying that it was the only major physical process associated with the Messinian Salinity Crisis or that it was necessarily the most important.

The Gibraltar Sill has a depth of 320 m at present. This is sufficiently shallow to keep cold, deep Atlantic waters out of the Mediterranean, but not so shallow as to prevent the reflux of a higher salinity (38‰) intermediate water mass as a consequence of excess evaporation over river run off and precipitation in the Mediterranean region¹¹. Despite its great depth (> 3,000 m in places) the modern Mediterranean is thermospheric, that is, its bottom waters are everywhere warmer than 10 °C. Oceanic bottom waters on the other hand are psychrospheric, that is, 10 °C or less at depth. Some sediments of Eocene to Middle Miocene (Serravallian) age in the Mediterranean area contain psychrospheric ostracodes which, according to Benson¹², have their upper depth limits closer to the 8 °C than to 10 °C isotherm while those of Late Miocene (Tortonian and Messinian) age do not¹³. The marine sediments of latest Miocene age can therefore be regarded as deposits of a thermospheric sea.

The salinity crisis could not have been initiated until the Iberian Portal became shallow enough to cause the Mediterranean progressively to concentrate salt as a consequence of ending the present-day type of brine reflux. Once this stage was reached communication through the Iberian Portal would essentially be one way, and the balance between rate of supply and the rate of evaporation would dictate when and if drawdown would start in the now isolated Mediterranean¹⁴. Normal or near normal marine

planktonic faunas would perhaps persist for some time until increasing salinity led to their ultimate disappearance as when the Red Sea became isolated from the Gulf of Aden at 22,000 BP during the last ice age^{15,16}.

Before the total isolation of the Mediterranean, the Iberian Portal might have been a wide, shallow channel through which a permanent current flowed from west to east. One of us (W.B.F.R.) suggests that in response to eventual drawdown of the Mediterranean, the portal may have evolved into a series of interconnected marine waterways lying at different base levels relative to the Atlantic and separated by cataracts. Evaporation along the route through the portal may have been minimal accounting for the observation of H. Dronkert in the Vera Basin of southern Spain of shallow-water corals and bioherms sandwiched between Messinian gypsum with bird tracks on bedding planes¹⁷ and deep-water pelagic marls and turbidites containing *Globorotalia conomiozea*¹⁸. Parts of the cascading passageway would eventually have been subjected to tectonic modification and subaerial erosion before its remnants were filled with Pliocene or later marine sediments.

There are several supposedly continuous Miocene/Pliocene marine successions in the Mediterranean region (Chelif Basin, Algeria; the circum-Troodos area of Cyprus; and the central and western parts of Crete) which on present evidence do not seem to support the deep basin desiccation hypothesis as formulated after the 1970 deep-sea drilling cruise² and later sustained by further drilling in 1975 (ref. 19). Of the land areas mentioned above, the first two are inadequately known and the third is not noted for the quality of its exposures and faunas at the critical

level. These anomalies require further careful investigation as does the succession recently described by Montenat *et al.*²⁰ in the Vera Basin, Spain.

The flow of normal marine water through the shallow Iberian Portal envisaged above, would have been affected by changes in sea level. A substantial global fall might have led to a total restriction of the Mediterranean and to consequent desiccation^{21,22}. Thus, it is pertinent to examine the available sedimentary and faunal evidence for Late Miocene alterations in global sea level.

The deposition of shallow-water marine carbonates (inter-tidal, subtidal, platform and shelf facies, etc.) was a normal and continuing process within the circumtropical zone throughout most of Cenozoic time, fossiliferous limestones of Palaeocene to Middle Miocene age being common in the central Americas, Mediterranean and Indo-Pacific regions. Upper Miocene limestones are, however, rare everywhere^{23,24}, and there seem to be no described shallow-water carbonates spanning the Miocene/Pliocene boundary. Even in the Pacific (for example, Bikini and Eniwetok atolls) where continuous deposition across this boundary was once thought to have occurred^{25,26}, reappraisal of the foraminiferal faunas has shown that assemblages characteristic of the latest Miocene are absent²⁷. In the Capricorn Basin of NE Australia, a faunal and physical break has been demonstrated between shallow-water carbonates of N14 and N19 age in the Wreck Island Bore²⁷, while in the off-shore part of the Carnarvon Basin, western Australia, a major disconformity separates the shallow-water N13 carbonates penetrated in the Tryal Rocks No. 1 bore from the overlying limestones of N18 age²⁸. The most comprehensive review of the stratigraphical succession in Indonesia²⁹ includes no examples of limestones spanning the Miocene/Pliocene boundary. Baumann³⁰ has, however, recently published a diagram (ref. 30, Fig. 2) showing this boundary within the Karren Limestone of NE Java but without adducing any supporting data. There is, in fact, no faunal evidence that any part of the limestone is Miocene, and, if it were, it would still be necessary to prove continuous deposition across the Miocene/Pliocene boundary in order to affect the present argument. A recently completed study of the Miocene/Pliocene succession in Viti Levu, Fiji (Adams and Rodda; in preparation) proves that an angular unconformity separates N17 from N18/19 sediments. A clearly recognisable stratigraphic hiatus exists on the Sea of Japan side of Honshue (Lloyd H. Burckle, personal communications). The Caliza Tosca, a shallow-water limestone some 60 m thick in Andalusia, Spain, is generally regarded³¹ as Messinian in age and therefore coeval with the Mediterranean evaporites. This age determination, however, is based on stratigraphic position and the absence from a critical sample (C12) of *Discoaster quinqueramus*, rather than on positive evidence, and is therefore questionable. There seems to be no palaeontological proof that it is not early Messinian, that is, pre-evaporitic. The thick succession of carbonates and evaporites which make up the Bahamas Platform in the West Indies extends from the Recent down at least to the Lower Cretaceous, but the Andros deep well (14,585 feet) yielded no evidence for the position of the Miocene/Pliocene boundary³² and none for or against continuous carbonate deposition throughout the Late Miocene.

Examination of the Upper Miocene—Lower Pliocene carbonate-clastic sequence in northern Florida, USA³³ shows a pronounced erosional unconformity between the Choctawhatchee Formation (N17) and the overlying N19 sediments. In southern Florida, the Tamiami Formation, a shallow water carbonate unit, is broken by an unconformity separating N17 from N19 sediments³⁴. A similar unconformity occurs in the coastal plain of Maryland, Delaware and New Jersey separating yellow-white glauconitic sands and silts of the Yorktown Formation of latest

Fig. 2 Hypothetical migration of the locus of shallow-water carbonate deposition towards the shelf-edge during the suggested Messinian age eustatic sea-level fall of 40–70 m in the world ocean.

Miocene to Pliocene (?) age from bluish-grey clay belonging to the St Mary's Formation of Middle Miocene age^{35,36}.

Since shallow-water deposits of the type we have been referring to are deposited within the photic zone, a fall in the level of the world ocean would ensure that their area of deposition migrated towards the edge of the continental shelves. The greater the eustatic drop, the farther the zone of deposition would move. Nearshore limestones of pre-Messinian age would either be eroded or buried by clastic sediments deposited in brackish or freshwater milieux. New limestones would form farther away from the old coast lines (Fig. 2) and, where sedimentation was continuous, would rest on somewhat deeper-water sediments of Tortonian age. Changes in sedimentation would occur across the continental shelves of the entire world, and the lowering of sea level would be reflected in their faunas. Only where considerable uplift has occurred could such limestone be found on the land surface today.

The possibility of a Late Miocene eustatic change is also suggested by the facies changes in ostracode faunas and sediments of the Caribbean and on the Atlantic Coast of the United States. The ostracodes of these regions are well known (refs 37, 38). Of special interest are those from Blow's zones N13 to N21 from Cuba, Hispanola, Puerto Rico and Trinidad, although faunas of the same age and latitude are known from Central America. In almost every case the palaeoenvironmental succession indicates a rapid shallowing upward from N16, often followed by a hiatus, then by a deepening. The exceptions occur in Panama, where the deposition of the shallow Gatun Formation was followed by continental deposition, and in Costa Rica, where shallowing was slow and continuous. Often the stratigraphic control of these shallow beds is through inference or benthic microfaunal successions as planktonics are rare. In Trinidad, the Springvale Formation is a clay-glaucconitic sand mixture; carbonates of N17 age are rare, stratigraphically doubtful or absent. The Jamaican section is carbonate, but deep; it nevertheless shows noticeable shallowing during the Late Miocene.

There is good evidence from widely separated areas that marked faunal and floral changes occurred during the late Miocene. In California^{39,40,41}, Alaska⁴², the Atlantic⁴³, the Pacific⁴⁴, the Antarctic and southern oceans where foraminiferal assemblages and the isotopic composition have suggested^{45,46} both cooling and a drop in sea level. There is also evidence from the land floras from a cooling in the Late Miocene of NW America⁴⁷.

The benthic foraminiferal fauna of the south Florida Tamiami Formation, underlying the N17–N19 unconformity indicates a shoaling environment which became increasingly restrictive with time³⁴. This fauna is replaced by a lacustrine diatom assemblage at the Miocene/Pliocene boundary. Rocks of the same age in northern Florida also indicate a prograding succession of events that may also be due to a Late Miocene drop in sea level³³.

Changes in the frequency^{42,48}, coiling direction^{49,51} and $\delta^{18}\text{O}$ composition of planktonic foraminifera indicate an influx of cold water into the New Zealand area during a

stratigraphic interval known locally as the Kapitean stage. Reinterpretation of the palaeomagnetic stratigraphy on the Mangapoi and Blind River sections⁵² suggests that regressive sediments and discontinuities in the Kapitean are time correlative⁵ with the Messinian stratotype of Sicily. Coiling ratios from strata off NW Australia referable to zone N18 also indicate cooling of the higher latitude seas at the close of the Late Miocene.

This cooling and accompanying regression have been attributed to an expansion of Antarctic glaciation leading to a fall in sea level of perhaps 50–70 m, recognisable during the later part of the Andalusian³¹ and consistent with the magnitude of ice volume change recorded in the $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ isotopic data on *Uvigerina* from DSDP Site 284, south Pacific⁴⁵.

A substantial fall in the level of the world ocean, that is more than about 50 m, would be sufficient to convert some shallow shelf areas into inland lakes. The Sea of Japan would be isolated by a fall of 70 m, and it would be interesting to learn whether evidence for freshwater sediments of late Miocene age has been obtained from drill holes in this area.

The lowering of global sea level could have been the event which closed off the Iberian Portal, leading to the Mediterranean isolation and eventual desiccation^{10,33}. Conversely, the extraction of 6% of the dissolved salts in the world ocean brought about by the Mediterranean desiccation⁸ could have induced the late Miocene glaciation by lowering high latitude salinity sufficient to raise the freezing point of seawater. Other possible effects of the massive salt extraction are the abrupt change in the percentage carbonate (relating to the dissolution of calcareous tests) occurring in drill holes in the Pacific, Atlantic and Caribbean areas at a stratigraphic level very close to the boundary between Upper Miocene and Lower Pliocene sediments⁵ and the apparent absence of even shallow-water limestones at that time²⁴. It may be more probable, however, that the onset of glaciation was independent of Mediterranean events, and high latitude cooling was the principal mechanism to cause areas of carbonate deposition to migrate away from the land.

Precise dating of these numerous events of the Late Miocene is fraught with difficulties because of the short period of time involved and the consequent imprecision of stratigraphical correlation using palaeobiological methods. A general lowering of sea level, however, of the order of 40–70 m would certainly have had a dramatic effect on the sediments and faunas of the continental shelves. Evidence of this should be preserved in bore-hole records, the investigation of which could reveal the duration and order of magnitude of any change. The Tortonian/Messinian eustatic-fall hypothesis is therefore eminently testable and can be verified or refuted by stratigraphers with access to drilling records in such areas as the Gulf of Mexico, China Sea and Persian Gulf.

Evidence for a sensitising pigment in fly photoreceptors

K. Kirschfeld & N. Franceschini

Max-Planck-Institut f. biol. Kybernetik, Spemannstrasse 38, 7400 Tübingen, West Germany

B. Minke

Department of Physiology, Hebrew University-Hadassah Medical School, Jerusalem Israel

Many photoreceptor cells in invertebrates have a dual-peak spectral sensitivity. Evidence is presented that in fly photoreceptors the ultraviolet peak is due to a photostable pigment that absorbs light quanta and transfers the energy to the blue-absorbing visual pigment.

The primary process induced by absorption of a light quantum in a visual-pigment molecule is the isomerisation of the chromophore retinaldehyde from the 11-*cis* to the all-*trans* form¹. Subsequent dark reactions finally lead to an excitation of the receptor cell. We present here evidence that in addition to this direct interaction between light and visual pigment,

another process can take place—the light quantum can be absorbed by an accessory pigment which then transfers the energy to the visual pigment. The photostable accessory pigment is therefore acting as a 'sensitising pigment'. Sensitisation is known in photography where it is used to extend the spectral sensitivity of silver halides². In plant cells also, photostable accessory pigments (for example carotene) absorb light and transfer the energy to the effector pigment, chlorophyll *a*, for use in photosynthesis³.

Fly photoreceptors

In the compound eye of flies six of the eight receptor cells in each ommatidium have a receptor-potential action-spectrum with two maxima of similar height, one close to 500 nm, the other in the near ultraviolet, close to 360 nm (refs 4, 5). Dual-peak sensitivity of this type cannot be explained on the basis of extinction spectra of known rhodopsins: these pigments have only a small peak at shorter wavelengths, of less than 25% of the maximum (β -peak)⁶.

On the basis of electrophysiological experiments using selective chromatic adaptation, Burkhardt⁴ concluded that there was only one visual pigment present in each photoreceptor. Later data were thought to suggest the existence of two different rhodopsins and metarhodopsins in one and the same receptor cell^{5,7}, but the most recent results⁸ again support the view that there is only one visual pigment in these receptors.

Receptor-potential recordings are not a direct method of characterising visual pigments, for two reasons, first, it is not possible to exclude electrical interactions between different receptor cells with any certainty; and second, it is not possible to discriminate between effects of visual pigment *per se* and effects of accessory pigments which could modify the properties of photoreceptors in several ways⁹.

Microspectrophotometry provides more direct data on visual pigments. Difference spectra in receptors 1 to 6 have been measured in the visible range ($\lambda = 400\text{--}700\text{ nm}$)^{10–13}. These data (from *Calliphora*) show that there is only one isosbestic point at 510 nm, irrespective of which combination of two wavelengths of the spectrum is used for the conversion of rhodopsin into (dark-stable) metarhodopsin and *vice versa*. The difference spectrum is consistent with the existence of a rhodopsin with peak absorption at 490 nm, which nicely fits the spectral sensitivity in the visible, and a metarhodopsin with peak absorption at 580 nm. The fixed isosbestic point also indicates that there should be only one visual pigment in these receptors. But, it does not exclude with certainty the existence of a second visual pigment, since this could be non-absorbing in the limited spectral range investigated so far, or its spectrum could strongly overlap that of its metarhodopsin and hence exhibit a null difference spectrum. Results from microspectrophotometry so far give no explanation for the high ultraviolet sensitivity measured electrophysiologically.

Since there must be absorption of light in the ultraviolet if the receptor cells show high ultraviolet sensitivity, we decided to record not only the difference spectrum but also an absolute spectrum and to extend the measurements into the ultraviolet spectral range.

Microspectrophotometry

For microspectrophotometry, dipteran photoreceptors have the advantage that—in contrast to the situation in for example, locust or bee—the rhabdomeres in each ommatidium are not fused together but are separated from each other over their whole length, so that they act as individual light guides. It is therefore possible to measure the extinction of individual rhabdomeres in an eye cup preparation as was first done by Langer¹⁴. These structures are only 1–2 μm in diameter, so waveguide effects slightly modify the measured extinction spectra; however, this minor effect¹⁵ is within the limits of error of our data and no correction was applied.

Figure 1a shows two extinction spectra of type R_{1-6} receptors

Fig. 1 *a* and *b*, Extinction spectrum of rhabdomeres type R_{1-6} (*Musca* ♀, eye-cup preparation of a white-eyed mutant) as measured with a technique similar to that of Langer¹⁴, but using a single beam instrument (Leitz MPV2, with Zeiss ultrafluor-optics, selected for minimal chromatic aberration). During measurements in the spectral range from 440–660 nm the preparation was illuminated with strong adapting lights of 365 nm (○) or 583 nm (●) at regular intervals, in order to maintain a stable equilibrium of rhodopsin/metarhodopsin. During adaptation the photomultiplier was protected by a mechanical shutter. Since other experiments showed that there is only a slight change or no change in extinction for wavelengths shorter than 430 nm after ultraviolet or orange adaptation, the spectrum in this range was measured without adaptation (×). ○, ●, ×, Data from rhabdomeres no. 2, 3 and 4 (measured together) of one ommatidium. In order to get a more accurate spectrum in the ultraviolet, rhabdomeres (no. 4 and 5) from 5 ommatidia of another eye were measured and the mean spectrum of all 6 ommatidia calculated (*b*); the given standard error was obtained after shifting the spectra along the ordinate to coincide at $\lambda = 440\text{ nm}$. Zero extinction is not defined in this kind of measurement, since the measuring beam passes the convergent cornea-lens of the ommatidium, whereas the reference beam does not. The cornea was shown to transmit uniformly in the spectral range analysed and fluorescence did not affect the measured spectra. Temperature of the preparations was 6–8 °C. Inset: cross section through ommatidium indicating receptor cells RC and rhabdomeres Rh. *c*, Difference of spectra from *a* (▲). Additional measurements at the short wavelengths (Δ) were carried out in the same rhabdomeres. Other rhabdomeres R_{1-6} sometimes showed reproducible small negative differences in the ultraviolet.

from a white-eyed *Musca* ommatidium, adapted with orange ($\lambda = 583\text{ nm}$) and ultraviolet ($\lambda = 365\text{ nm}$) light, respectively. It is obvious that there is a high extinction in the ultraviolet, which is confirmed by data from five more ommatidia (Fig. 1*b*). A second maximum occurs either near 500 nm or near 560 nm, respectively, depending on the pre-adapting light. The difference (Fig. 1*c*) between the two curves of Fig. 1*a* represents the difference spectrum between metarhodopsin (M 580) and rhodopsin (R 490), which corresponds to that obtained in intact animals¹¹ and in wild-type flies (*Calliphora*)¹³. We have confirmed that the difference spectrum in *Musca* changes only in amplitude, not in shape, when the wavelengths used for shifting the pigment from one stable state (R 490) to the other (M 580) are changed, and we have extended the measurements into the ultraviolet.

In spite of the fact that there is a high absorption in the ultraviolet (Fig. 1*a, b*) and that ultraviolet light induces a shift from rhodopsin to metarhodopsin, there is no conspicuous

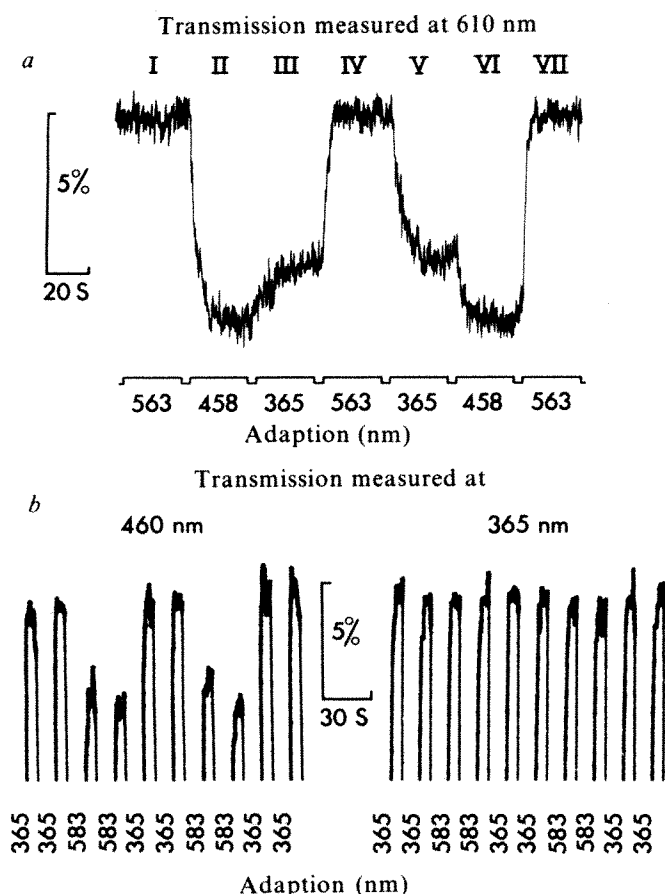

Fig. 2 *a*, Transmission of rhabdomeres no. 2+3+4 (*Musca* ♀, white-eyed) measured at 610 nm. Adapting lights of different colours were used as indicated. Appropriate edge filters prevented transmission of adapting light to the photomultiplier. *b*, Transmission measured in the blue (460 nm) and ultraviolet (365 nm) following various adapting lights as indicated. In contrast to Fig. 2*a* the adapting light was switched off during the measurement.

decrease in the ultraviolet extinction. As this result was unexpected we checked directly whether the blue and ultraviolet lights shift the pigment to the same or to two different metarhodopsins, both absorbing in the red. The temporal change in metarhodopsin concentration was monitored by measuring transmission at 610 nm: the higher the transmission, the lower the metarhodopsin concentration (Fig. 2*a*).

After an equilibrating pre-adaptation with 563-nm light which shifts the pigment to the rhodopsin state, both blue (458 nm, Fig. 2*a* I→II) and ultraviolet (365 nm, Fig. 2*a* IV→V) lights shift the pigment back to metarhodopsin, as indicated by the reduction in transmission at 610 nm. The equilibrating blue light shifts more than the equilibrating ultraviolet light.

In fact, ultraviolet light following blue light (Fig. 2*a* II→III) leads to a conspicuous increase in transmission at 610 nm. If there had been two different red light-absorbing metarhodopsins in the one photoreceptor, this ultraviolet stimulus should have led to a further decrease in transmitted red light, due to the formation of the second metarhodopsin. The observed increase indicates that, during ultraviolet illumination, a new equilibrium between rhodopsin and metarhodopsin is created which yields less metarhodopsin than does blue illumination. These results are evidence that the metarhodopsin formed by ultraviolet light is the same as that formed by blue light.

Figure 2*b* illustrates directly the fact that ultraviolet light following orange (583 nm) light reduces the rhodopsin concentration, as shown by an increase in transmission in the blue (460 nm), despite the fact that there is no change or only a slight change, in ultraviolet absorption in equivalent conditions (Fig. 2*b*).

The results obtained with microspectrophotometry can be interpreted in at least three ways. (1) There is a second visual pigment that absorbs in the ultraviolet, and has a metarhodopsin also absorbing in the ultraviolet. Their strongly overlapping spectra would explain the odd absence of extinction change in the ultraviolet (Fig. 1). (The shift of pigment to M 580 by ultraviolet illumination is then due to the β peak of R 490). (2) The rhodopsin and metarhodopsin are unusual insofar as they both absorb strongly in the ultraviolet. (3) There is a photostable pigment absorbing in the ultraviolet and transferring the energy to the rhodopsin. It then acts as a sensitising pigment.

One possible mechanism of energy transfer is by means of dipole-dipole interactions (case 3*a*), according to Förster's theory¹⁶. In this case the photostable pigment is called an 'antenna' pigment, as in photosynthesis. Other kinds of energy transfer are also possible, for example, a photostable chromophore could be attached to the rhodopsin molecule, giving rise to a high ultraviolet absorption in rhodopsin (as well as in metarhodopsin) (case 3*b*). Such a mechanism, in a way, is rather similar to the situation in photographic sensitisation, in which a dye must be adsorbed on to the silver halides in order to act as a sensitiser². The trivial case in which light quanta, emitted due to fluorescence of a photostable substance, are reabsorbed by the rhodopsin seems rather unlikely because of the low efficiency of this process within a rhabdome.

According to electrophysiological data, hypothesis (1) is improbable, since intracellular recordings made in cells 1-6 under selective chromatic adaptation have revealed that blue-light adaptation depresses sensitivity in the blue and the ultraviolet to the same extent and vice versa^{4,8}. We present here experiments that exclude hypothesis (2) as well as (1) and give evidence that hypothesis (3) is realised.

Evidence for a sensitising pigment

The sensitising-pigment hypothesis can be formulated as follows:

Due to the absorption of a light quantum, the unspecified molecule X is converted into the excited state X^* (equation 1). In a secondary process it then may interact with a rhodopsin molecule R , converting it into an excited state R^* (equation 2), which finally leads to metarhodopsin M (equation 3). Alternatively, the molecule X^* may lose the extra energy by fluorescing

or by suffering deactivating collisions with other molecules. In the latter case the energy is dissipated as heat. If the energy transfer occurs by means of a dipole-dipole interaction (case 3*a* as discussed above), the concentration of the molecules present determines whether the secondary process occurs according to equations (2) and (3) or to equation (4), assuming that the lifetime of the excited state is sufficiently short. This is because these concentrations affect the probability that a molecule X^* meets a molecule R ¹⁷. The relationship between the percentage of rhodopsin still present and the number of bleaching quanta should be a decreasing exponential for blue as well as for ultraviolet quanta, as long as the concentration of R and X is comparatively high, since the kinetics in both cases corresponds to classical first-order photochemical bleaching.

But, if we reduce sufficiently the concentration of X and/or R we expect to observe the following two phenomena: (1) The ratio of the number of ultraviolet quanta to blue quanta necessary to shift a given percentage of rhodopsin into metarhodopsin must be increased with a sufficiently decreased concentration of R and/or X . (2) An exponential decrease of rhodopsin concentration due to bleaching is still expected for blue light,

Fig. 3 *a*, Initial part of electroretinograms on a rapid time scale obtained with high-energy orange test flashes of constant intensity from a white-eyed *Drosophila* raised on Sang's synthetic diet medium²⁴ with 2.4 mg per 100 ml β -carotene added (8 mg per 100 Δ 100%). The flash light-source (photographic flash, Braun F 900) was used in conjunction with a Schott OG 590 edge filter and a Schott KG1 heat filter. The energy of the flash when using a monochromatic 584-nm interference filter (Schott, Depal) together with KG1 heat filter, was 5.4×10^{16} photons cm^{-2} at the level of the preparation. Before each measurement the eye was given two orange flashes that shift the pigment to the rhodopsin state. After 1 min in the dark the amount of monochromatic 362 nm ultraviolet light (Schott, uv-pil) indicated on the left of each trace was applied. After 1 min in the dark the orange test flash (590 nm) of constant intensity was given, inducing the five responses shown. Each orange flash elicits a mass response composed of several components indicated by numbers on the third trace: 1, stimulus artefact, indicating the onset of the flash; 2 and 3, biphasic fast photovoltage proportional to the concentration of pigment in the metarhodopsin state. This response called the M-potential, can be subdivided into a negative phase (2) and a positive phase (3)¹⁸. 4, 'on' transient of the ERG which arises from the response of the second-order neurones. *b*, The ordinate gives the difference between the peak M-potential amplitude following saturating ultraviolet light (M_{sat} , bottom M-potential trace in *a*) and the M-potential amplitude $M(I-t)$ following various amounts ($I-t$) of adapting 362-nm ultraviolet (●) and 473-nm blue (○) light. The curve actually represents the decay of rhodopsin concentration as a function of the amount of adapting light.

but no longer for ultraviolet light. This is because the concentration of rhodopsin, further reduced by an increasing number of absorbed ultraviolet quanta, reduces the efficiency or energy transfer between X^* and R. The kinetics can then no longer be first order.

To test these predictions we measured the concentrations of fly visual pigments by an electrophysiological technique. This independent and sensitive method has the advantage of using intact flies whereas the microspectrophotometric measurements were carried out with eyecup preparations. The pigment conversion in receptors R_{1-6} was measured by a fast photovoltage, the M-potential¹⁸, which is a response proportional to the metarhodopsin concentration [M] in R_{1-6} , as shown by the following evidence. (1) The action spectrum of the M-potential corresponds to the metarhodopsin extinction spectrum of receptors R_{1-6} (ref. 18). (2) No M-potential has been observed in mutants lacking receptors R_{142} (S. R. Grabowski and W. L. Pak, personal communication). (3) In a dark-adapted eye, the M-potential amplitude increases exponentially with the amount of incident blue quanta and reaches saturation at the same level at which metarhodopsin formation saturates (Minke *et al.*, unpublished).

M-potentials were recorded from a white-eyed *Drosophila* with an approximately normal rhodopsin concentration, in

response to a strong orange test flash, following various amounts of 362-nm ultraviolet pre-adapting light (Fig. 3*a*). Figure 3*b* shows a plot of the difference between the M-potential from rhodopsin to metarhodopsin. This experiment is a control amplitude measured after an equilibrating ultraviolet illumination and the M-potential amplitude measured after different amounts of pre-adapting ultraviolet light. This method of presentation actually illustrates the decay of rhodopsin concentration [R] with increasing ultraviolet illumination, since $[R] = 1 - [M]$.

Equivalent data for 473-nm blue adaptation are also included in Fig. 3*b*. The data show that the rhodopsin concentration decreases exponentially with the amount of adapting blue or ultraviolet light. In this case the 362-nm ultraviolet light is as efficient as the 473-nm blue light in shifting the visual pigment from rhodopsin to metarhodopsin. This experiment is a control experiment for normal flies. In the critical experiment we need flies with rhabdomeres in which the concentrations of rhodopsin and/or the presumed sensitising pigment are reduced.

The concentrations of rhodopsin within the rhabdomeres can be reduced by raising flies in a vitamin A-deficient medium^{12,19,21,22}. Figure 4 shows the decay of the rhodopsin concentration, again measured by the M-potential, as a function of the amount of adapting 473-nm blue and 362-nm ultraviolet light, measured in a vitamin A-deprived fly. First, it seems that about twice as many ultraviolet quanta as blue quanta are now necessary to produce a criterion M-potential of 50% of the maximum (in three other experiments two to nine times as many ultraviolet quanta were necessary). Second, the dependence of the rhodopsin concentration on the amount of adapting ultraviolet light is no longer exponential. This is in contrast to the dependence on blue-adapting light (measured in the same fly), which remains exponential.

Thus in vitamin A-deprived flies, the effectiveness for converting rhodopsin into metarhodopsin is selectively reduced in the ultraviolet. This is in agreement with the result that the sensitivity of the receptors as determined with the ERG in vitamin A-deprived flies is selectively reduced in the ultraviolet^{19,23}. This finding, as well as the fact that the kinetics of the decrease of rhodopsin concentration under ultraviolet illumination no longer corresponds to a first-order reaction, fits the predictions of the 'antenna' pigment model.

Fig. 4 Concentration of pigment in the rhodopsin state, as measured by the M potential, in response to the orange test flashes of constant intensity, as a function of the amount of adapting 362-nm ultraviolet (●) and 473-nm blue (○) light. All the measurements were from a single white-eyed *Drosophila* raised on vitamin-A-deficient medium (Sang's synthetic diet medium with 0.8 mg per 100 ml β -carotene). The vertical bars are standard deviations of the mean calculated from three or four measurements. Most of the points without bars are the average of two measurements.

Our results are not compatible with the hypothesis of a second rhodopsin-metarhodopsin, absorbing in the ultraviolet (model 1). This model would predict neither the high efficiency of ultraviolet quanta for the production of M 580, as shown in Fig. 3b, nor the modifications seen in flies raised on vitamin A-deprived media (Fig. 4). An unusual rhodopsin (model 2) would also be unable to generate the modifications observed in vitamin A-deprived flies. Although the antenna-pigment model is sufficient to explain the experimental results, this kind of sensitisation is not necessarily the only possible one. With several special assumptions, a mechanism of energy transfer according to case 3b, as mentioned above, could also be realised. There is some evidence that the absorption in the ultraviolet is due to a derivative of vitamin A (J. Schwemer, personal communication). If this substance is attached to all rhodopsin molecules as a second chromophore only at sufficiently high vitamin A concentrations, then at lower vitamin A concentrations, two populations of rhodopsin will be present: one with a high ultraviolet absorption due to the second chromophore, and another which lacks the second chromophore and therefore has only low ultraviolet absorption (due to the low β peak of the rhodopsin). The kinetics of the decay of both rhodopsins will be the same if blue light is used for bleaching. There will be two different decay rates, however, if ultraviolet light is used, since the absorption coefficients of the two substances differ in the ultraviolet. This is also in accordance with Fig. 4 (ultraviolet illumination), since the deviation from the pure exponential can be interpreted as being due to the sum of two exponentials with different decay constants.

We conclude that the photoreceptors 1-6 in the fly achieve their high ultraviolet sensitivity thanks to an accessory photostable pigment that acts as a sensitiser for rhodopsin. The mechanism of the energy transfer has still to be worked out in detail. The functional consequence of the sensitising pigment for

the photoreceptors is clear—it broadens the spectral range of the visual pigment and thus increases absolute sensitivity.

We thank Drs E. Buchner, K. G. Götz, K. Hamdorf, P. Hillman, S. Hochstein, B. Pick and C. Wehrhahn for discussions, Mr R. Feiler for technical assistance, Mr M. Heusel for preparing the figures and Dr P. McIntyre for reading the manuscript. This research was supported in part by a grant from the United States-Israel Binational Science Foundation, Jerusalem, Israel (to B.M.).

Nucleotide sequences of 5'-terminal ribosome-protected initiation regions from two reovirus messages

Marilyn Kozak

Roche Institute of Molecular Biology, Nutley, New Jersey 07110

Sequences for two reovirus ribosome-protected fragments are presented. Comparison with four other reovirus initiation sites reveals only two common features: the 5'-terminal sequence m⁷GpppG^mCUA, and (located 15-33 nucleotides from the cap) the sequence AUGG. Both the cap and the AUG codon are included in the 40S-ribosome protected region from all six reovirus messages.

THERE has been considerable speculation about what features in mRNA direct attachment of ribosomes to the sites where translation will be initiated. Although rather sophisticated hypotheses have been advanced for messenger-ribosome interactions in prokaryotic systems^{1,2}, deductions about eukaryotic mechanisms have been limited by the absence of detailed information concerning the initiation sites from a variety of eukaryotic messages. The sequence extending from the 5' capped terminus up to and beyond the AUG initiation triplet was reported for one of the genome segments from brome mosaic virus³ and, more recently, for rabbit β -globin mRNA^{4,5}. We have previously described the nucleotide sequences of ribosome-protected regions from four reovirus messenger RNAs^{6,7}. We present here sequences for two additional reovirus ribosome binding sites. All six ribosome-protected frag-

ments from reovirus mRNA include the 5'-terminal methylated cap, which has been shown to strongly promote *in vitro* translation of various eukaryotic messages⁸.

Isolation of two ribosome-protected fragments

Reovirus mRNAs, labelled with α -³²P-ribonucleoside triphosphate precursors, were synthesised *in vitro* by virion-associated enzymes, in conditions described previously⁶. The *in vitro* transcription reaction catalysed by reovirus cores generates 10 presumably monocistronic messenger species which can be fractionated by sucrose gradient velocity sedimentation into small, medium and large size classes⁹. In this study, the small size class (s-RNA), consisting of four messenger species, was incubated in a wheat germ extract in conditions permitting formation of both 40S and 80S initiation complexes^{6,7}. After addition of T₁ RNase to hydrolyse the exposed regions of the RNA, the samples were sedimented through glycerol gradients^{6,7}. The ³²P-labelled material recovered from 40S ribosomal complexes consisted of a mixture of three cap-containing fragments, which were readily resolved by polyacrylamide gel electrophoresis followed by two-dimensional homochromatography⁷. Nucleotide sequences were previously determined for two of these s-RNA fragments⁷ (s54 and s45 in Fig. 1). The following section describes the sequence of the third fragment, designated s46; that is, a 46-nucleotide fragment

Nucleotide sequence of fragment m30

The T₁ RNase fingerprint of fragment m30 is shown in Fig. 2c and d. The sequence of each primary T₁ RNase product was deduced from the results of secondary digestion with pancreatic RNase, summarised in Fig. 4a. For the large oligonucleotide m30/T2, the sequence was confirmed by analysis of the U₂ RNase digestion products (Fig. 3c). Figure 4b summarises data on the primary pancreatic RNase products. Presence of panc oligonucleotide P5 (AG), which terminates with a G residue rather than with a pyrimidine, identifies T₁ oligonucleotide T4 (CAG) as the 3'

Fig. 3 Sequence analysis of fragment s46. The column headings α-³²P-CTP, α-³²P-UTP and so on indicate the labelled ribonucleoside triphosphate precursor. A double dash in any column means that the oligonucleotide in question was not labelled in the indicated conditions. The designation n.d. means a given analysis was not done. * Denotes the 3'-nucleoside monophosphate which retained the ³²P-radioactivity after alkaline hydrolysis. 'Cap' refers to the structure m7GpppG^mpCp, identified as in ref. 7. The nearest neighbour residue is enclosed in square brackets at the 3' end of each oligonucleotide. The sequence deduced in a for oligonucleotide s46/T2 takes into account the results described in c. In c, the secondary U₂ RNase products are identified as (a), (b) and (c), in order of increasing mobility on DEAE paper in 7% formic acid. The column headed 'Panc/CMCT products' lists the products obtained by pancreatic RNase digestion of each U₂ secondary product after modification of U and G residues with CMCT⁶. In d, the third column lists the T₁ oligonucleotides (identified as in a) obtained after complete T₁ RNase digestion: the products of secondary pancreatic RNase digestion are given in parentheses next to each T₁ oligonucleotide.

terminus of the ribosome protected fragment. Ordering of the remaining T₁ oligonucleotides is facilitated by beginning with T3, the only T₁ oligonucleotide that begins with a U residue. T3 must be preceded by P2 which is the only G-containing panc oligonucleotide that terminates with U. Since T3 ends with the sequence G[G], it is followed by P1 (GGC[U]), the only remaining panc oligonucleotide containing contiguous G residues. The resulting sequence, (5')GGUCAUGGCU(3'), must be followed by T2, which begins with CU. Furthermore, the 5' side of the sequence can be extended by adding one C residue, since oligonucleotide T5 (CG[G]) is the only remaining T₁ product that terminates in G[G]. Oligonucleotide T4 has already been placed at the 3' terminus of the fragment, leaving only the capped oligonucleotide T1, which obviously derives from the 5' end of the fragment. The complete 30-nucleotide sequence is shown at the top of Fig. 4.

Features of reovirus ribosome-binding sites

The two sequences described above, along with ribosome-protected portions of four other reovirus messages, are shown in Fig. 1. Each ribosome-protected fragment contains a single AUG triplet, with no termination codons following in phase. This AUG has not yet been proven to be the initiation codon, since the presence of blocked N termini in reovirus proteins¹⁴ has hampered amino acid sequence determinations. It is likely, however, that the single AUG triplet in each binding site is used for initiation, since the AUG occurs in a remarkably constant position within each 80S-protected fragment, as indicated in Fig. 1. The AUG triplet occurs in approximately the same position in the 80S-protected portion of rabbit β-globin mRNA¹⁵.

Each of the reovirus 5'-terminal fragments has been shown to rebind to wheat germ ribosomes with high efficiency^{7,10}, indicating that the isolated fragments retain the recognition signals needed for ribosome attachment. Thus, it is of interest to look for common features among the six reovirus sequences, as well as similarities with other eukaryotic initiation sites. Two of the reovirus fragments begin with the 5' terminal sequence m7GpppG^mCUAAAGU (see s45 and m44 in Fig. 1). In both of these fragments, the sequence GUC(or G)GUC occurs to the left of the AUG, and the sequence GCUUC follows directly after the AUG. The only part of this homology that occurs in other reovirus fragments is the sequence GCUU on the 3' side of the AUG codon in fragment m30. In fact, although fragment s45 differs, fragments m30 and m44 share an extensive 11-base sequence (GGUCAUGGCUU) that spans the putative initiation codon. A portion of this sequence (GGC... AUGGCU) also occurs in fragment s46, which further resembles m30 in that both fragments have the identical 10-residue 5'-terminal sequence. Thus, the 20-nucleotide sequence at the 5' end of fragment m30 is repeated (with two interruptions) in the first 25 residues of fragment s46. Such impressive homologies may reflect evolutionary relationships among reovirus genome segments, but the homologous regions are probably not directly related to the role of these fragments in initiating translation, since the same sequences are not seen in the remaining ribosome binding sites. Indeed, the only features common to all six reovirus initiation sites are a paucity of A residues, occurrence of a G residue directly after the AUG codon, and presence of the 5'-terminal sequence m7GpppG^mCUA. The

sequence G^mCUA adjacent to the cap is not seen, however, in many other messages, including brome mosaic virus RNA 4 (m7GpppGUAU)³, vesicular stomatitis virus mRNA (m7GpppA^mAC)¹⁶, silk fibroin (m7GpppA^mU^mC)¹⁷ and rabbit globin (m7GpppA^mC^mAC)¹⁸. The sequence AUGG, common to all six reovirus messages as well as globin mRNA^{4,5}, has the striking potential to form four base pairs with the anticodon loop (CCAU) of mammalian initiator tRNA²². In brome mosaic virus RNA 4, however, the AUG initiation codon is not followed by a G residue³. Thus, homology among the eukaryotic regions so far sequenced is limited to presence of an AUG triplet and a 5'-terminal cap.

It is difficult to detect any other significant features common to eukaryotic initiation sites. For example, eukaryotic ribosome binding regions differ from one another in that the AUG triplet does not always occur in the same phase, determined by measuring off three nucleotides at a time, from the AUG leftwards to the cap. The distance between the cap and the AUG also varies, from 11 nucleotides³ to at least 55 nucleotides^{4,5}. Furthermore, nonsense codons, which commonly occur on the 5' side of the initiation triplet in prokaryotic ribosome binding sites¹¹, are not a universal feature of eukaryotic initiation sites, since reovirus fragments s54, s46 and m30 lack such codons. The suggestion has been made that a specific interaction, involving a region near the AUG codon which is complementary to the 3' end of 18S ribosomal RNA, might be characteristic of eukaryotic (as well as prokaryotic) initiation sites². Between the reovirus 5'-terminal fragments and the 3'-terminal eight residues of 18S rRNA¹⁹, however, there are only minimal opportunities for base pairing (involving only two base pairs in fragments s54, s46 and m30; three base pairs in s45 and m44; and four A-U base pairs adjacent to the cap in fragment m52). Although absence of significant complementarity cannot be proved until additional portions of the 18S rRNA sequence

become known, there is no evidence in eukaryotic systems for even a moderately-stable, specific interaction between messenger and 18S ribosomal RNA. This seems to be true not only for reovirus, but also for the 5' non-coding regions of rabbit globin^{4,5}, brome mosaic virus³ and SV40 VP1 messages²⁰. Although base pairing with ribosomal RNA has been postulated for those three messages, the proposed interactions (involving primarily A-U base pairs, interrupted by unpaired residues in the case of SV40 VP1) are predicted to be far less stable than those demonstrated with prokaryotic messages². Furthermore, while the region postulated to undergo base pairing with ribosomal RNA is located in a rather constant position relative to the AUG in prokaryotic messages, this is not true of the eukaryotic initiation sites⁵. Thus, the suggestion that base pairing with ribosomal RNA might help to position the ribosome on eukaryotic messages seems to derive more from analogy with prokaryotic systems than from predication based on the available eukaryotic ribosome binding sequences. Although eukaryotic cellular mechanisms often parallel those observed with prokaryotes, perhaps the process of translational initiation is exceptional, due to the structural differences between prokaryotic and eukaryotic messages. With polycistronic prokaryotic messages, which require discrimination between the few internal AUG and GUG codons that actually serve for initiation and the much larger set of internal AUG and GUG codons which normally do not function as initiation triplets, a relatively intricate mechanism may be required for selection of the correct initiation sites by ribosomes. With monocistronic eukaryotic messages, on the other hand, initiation requires recognition of a single AUG codon, and inspection of the available eukaryotic sequences suggests that initiation begins at the AUG nearest the 5' end of the message. (Although the SV40 VP1 sequence²⁰ seems to be an exception, the possible occurrence of very limited processing of the VP1 protein, involving removal of a few N-terminal amino acids, would hamper the correct identification of the initiation region, which was based not on ribosome binding but on a comparison of the nucleotide sequence of the DNA with the amino acid sequence of the mature virion protein.) Inclusion of the 5' terminus as well as the AUG triplet within all six 40S ribosome-protected reovirus fragments is consistent with the possibility that these two elements are necessary features (recognition signals) in eukaryotic initiation sites. The absence of other detectable homologies among the limited set of eukaryotic initiation regions sequenced to date may mean that the presence of an AUG triplet near a 5' terminus (usually, but not necessarily capped) is sufficient to direct binding of eukaryotic ribosomes. This 'minimal recognition' hypothesis will undoubtedly require modification as more data becomes available. For example, if an AUG codon in the 5' region of an RNA molecule were masked by the surrounding secondary structure, that AUG might not mediate initiation unless a mechanism were available to denature the RNA. Furthermore, an AUG codon located extremely close to the 5' terminus, as in Sindbis 42S virion RNA (m7GpppAUG)²¹, would probably be non-functional because of steric considerations. We suggest, based on evidence to be published elsewhere, that the methylated cap functions secondarily, in a way that does not affect where the ribosome attaches to the message but that greatly increases the yield of initiation complexes. The secondary and tertiary structure of the intervening region, between the 5' terminus and the AUG triplet, might also be expected to influence translational efficiency by determining the spatial orientation of the two putative recognition elements. Thus, although the presence of an AUG codon near the 5' end of an RNA chain might be sufficient to permit a certain low level of ribosome binding, other structural features in the RNA probably modulate the initiation event.

I thank Dr Aaron Shatkin for helpful discussions and encouragement.

letters to nature

Identification of cosmic γ -ray sources CG135+1 and CG189+1 with HII regions

ELEVEN unidentified γ -ray sources have been reported by the COS B group¹ one of which was previously known from the SAS 2 satellite². Here, I point out two likely associations of the new sources with giant HII regions. CG135+1 lies in the direction of the complex of HII regions, OB associations, molecular clouds and dust in the Cas OB6 region of the Perseus arm. An H α photograph and identification chart for this region is given in ref. 3. The HII region W3 (IC1795) is located at ($l = 133.7^\circ$, $b = +1.1^\circ$), which is only 0.7° outside the one standard deviation error box for CG135+1 ($l = 135.5^\circ \pm 1.0^\circ$, $b = 1.5^\circ \pm 1.0^\circ$)¹. The SAS 2 longitude distribution⁴ is consistent with the existence of this source.

W3 lies at a distance of ~ 3.1 kpc in the Perseus arm⁵, and contains 10 infrared sources⁶⁻⁷, four condensed centimetre sources W3(A,B,C,D) (ref. 8) and an OH maser source⁸. A spectrum of W3(A) from 408 MHz– 10^{14} Hz is given in ref. 9. Krügel and Mezger¹⁰ suggest that W3 is an O-star association in a very early evolutionary stage, the component W3(A) consisting of a compact dense shell of ionised gas surrounded by a dense shell of neutral gas (density $\sim 10^4$ cm⁻³). The total infrared luminosity is $\sim 10^6 L_\odot$ (ref. 11); 1-mm observations¹² suggest a column density for W3 of 10^{23} H₂ molecules cm⁻², and an H₂ mass of $10^3 M_\odot$.

The reported intensity of CG135+1 is $\sim 2 \times 10^{-6}$ photons (> 70 MeV) cm⁻² s⁻¹ (ref. 13). If the cosmic-ray proton intensity is the same in W3 as locally, we can estimate the intensity of π^0 -decay γ rays using the source function given by Stecker¹⁴ to be $\sim 1.6 \times 10^{-10}$ photons (> 70 MeV) cm⁻² s⁻¹. Bremsstrahlung interactions may increase this by up to a factor ~ 2 (ref. 15) if the e/p ratio is the same in the cosmic-radiation flux near W3 as locally. Thus if the identification is correct, a density of cosmic radiation $\sim 10^4 \times$ the local density is required; this might be plausible if the sources of cosmic rays were associated with the young stars in the HII regions. The particles could either have been accelerated in the stars themselves, or in an associated supernova or SNR (the SNR HB3 is nearby and may be physically connected with W3^{16,17}). The association of W3 with the γ -ray source, however, could be attributed to an unseen γ -ray pulsar (there is no known radio pulsar in this direction) or an unknown γ -ray emitter connected with young stellar populations.

I also suggest the identification of the source CG189+1 ($l = 189.0^\circ \pm 1.5^\circ$, $b = 1.0^\circ \pm 1.5^\circ$)¹ with the HII region NGC2175 at $l = 190^\circ$, $b = +0.5^\circ$. Aperture synthesis observations of this object, and a report of an associated CO cloud 20 pc in diameter, have been published¹⁸.

NGC2175 has the same 6-cm flux density (30 Jy) as W3(A)¹⁹ and should have a similar infrared intensity to W3(A) if the proportionality of infrared to centimetre continuum applies¹¹. The positional coincidence here is in fact better than for W3.

The γ -ray source is extended in latitude¹, and also includes the direction to the SNR IC 443 ($l = 189^\circ$, $b = -3.2^\circ$)²⁰ which is an X-ray source²¹. The distance to both IC 443 and NGC 1275 is about 1.5 kpc, so that the possibility of a physical connection is not ruled out, in which case the situation may provide a case similar to that for W3 and HB3 discussed above.

If γ -ray emission is a common feature of objects like W3, other objects with similar radio and infrared fluxes should be γ -ray sources. Of the objects listed in refs 7 and 11, only W75 lies within the four areas examined by the COS B group¹. W75 ($l = 81.9^\circ$, $b = 0.8^\circ$) lies in the very densely populated Cygnus region in which the visibility of individual sources is rather low. The nearest γ -ray source is CG78.1 ($l = 78.5^\circ \pm 0.5^\circ$, $b = 1.5^\circ \pm 0.5^\circ$)¹.

The Orion complex (M42) should be easily observable if the W3 identification is correct, since it is about five times as intense both at 30–300 μ m and at 2 cm (ref. 11), and is in a region away from the Galactic plane where point-source visibility should be good. But it lies outside the four regions examined by Hermesen *et al.*¹, M17 is also a good candidate, being brighter than W3 in both infrared and radio; however, it is in the galactic plane at longitude 14.7° , and hence harder to distinguish from the galactic background.

I thank Professor A. W. Wolfendale for useful discussions and the Royal Commission for the Exhibition of 1851 for the provision of a Fellowship.

Tidal interactions and the massive halo hypothesis

THE idea that galaxies may be surrounded by large amounts of unseen material has become very popular. The arguments favouring such massive haloes are almost all based on the dynamical analysis of galaxies either individually or in groups, and they have been cogently assembled by Einasto *et al.*¹ and by Ostriker *et al.*². They concluded that galaxies may well be surrounded by large (~ 100 kpc) or very large (~ 0.5 Mpc) 'isothermal haloes' whose mass varies as the radius within which it is measured. (We take $H_0 = 50 \text{ km s}^{-1} \text{ Mpc}^{-1}$). Their views have subsequently received support from Arecibo observations which found flat HI rotation curves to very large radii for several spiral galaxies³, and from analyses of the dynamics of new samples of binary galaxies⁴ and of groups of galaxies⁵. The most extreme form of the massive halo hypothesis postulates very large haloes which are the dominant constituent of the Universe, and in which the observed galaxy is little more than contaminating debris left over from the formation of the unseen object⁶. It is disquieting that there seems to be little chance of direct observation of this dark material, and this letter points out that dynamical constraints can be put on either the extent or the universality of galactic haloes.

When a cluster of galaxies collapses and comes to equilibrium, the structure of the subunits which were its progenitors is rapidly broken up by the violent relaxation of the cluster as a whole⁷; similarly, if the individual galaxies in a group are too large, they may interact strongly enough that the whole group is soon smoothed into a single unit. Richstone showed that even if the galaxies in the core of the Coma cluster had once had sufficiently large haloes to contain the missing mass, their mutual interactions would by now have consigned 90% of the material to an intergalactic pool⁸. Galaxy-galaxy interactions are weakened by high encounter velocities in Coma, however, and should be much stronger in small groups where the velocity dispersion is of the same order as the internal dispersion of the individual galaxies: if the tidal destruction of galaxy-halo units has gone most of the way to completion in Coma, it may have gone entirely to completion in many groups.

The consequences of tidal interactions for the massive halo hypothesis are most easily discussed for binary galaxies. If haloes of almost unlimited extent form around most galaxies, the mass distributions of the members of a binary will overlap, and they may well orbit within a common envelope. Tidal effects will then cause the loss of orbital energy into internal energy and the merging of the observed galaxies. S.D.M.W. has recently carried out full N-body simulations of the interaction between pairs of 250-particle 'galaxies', and has found that if two equilibrium 'galaxies' are placed in a bound orbit in which their mass distributions significantly overlap, they merge very rapidly (compare ref. 9). The details of these calculations will be published elsewhere, but this statement may be quantified by noting that, for the near isothermal ($\rho \sim r^{-2}$) 'galaxies' studied, the condition $r_{\text{peri}} \lesssim 3r_i$ was sufficient for the binary to merge completely within one initial orbital time of its first close approach, where r_{peri} is the pericentric distance of the initial orbit and r_i is the half-mass radius of the initial 'galaxies'.

The dire implications of this result for the hypothesis of universal massive haloes can be seen from Fig. 1 which plots the quantity $N = \Delta v / (2)^{1/2} \pi H_0 r_p$ against magnitude difference for the 59 statistically selected binaries in Turner's sample⁴ (Δv and r_p are the observed velocity difference and projected separation); note that the galaxies in most of the pairs are of comparable magnitude. On the assumption of similar randomly-oriented circular orbits the median value of N is an unbiased estimator of the number of orbits the binaries have executed in a Hubble time (taken as H_0^{-1}); it should be close to the median number of actual orbits for the observed sample. The median pair has apparently execu-

Fig. 1 The Δm - $\log N$ distribution for the 59 binaries in Turner's sample. Δm is the magnitude difference between the pair members and N is the estimated number of orbits completed in a Hubble time. Errors in $\log N$ have been calculated for representative points using Turner's quoted uncertainties in Δv and r_p .

ted 13 revolutions since the beginning of the Universe: either Turner's binaries do not overlap substantially anywhere in their orbits, or they will spiral together in the next few billion years. Discounting optical pairs there are about 139 true binaries in the Zwicky catalogue satisfying all Turner's selection criteria; if their median remaining lifetime is equal to their median apparent orbital time, then roughly $13 \times \frac{1}{2} \times 139 \approx 900$ similar pairs should have merged in the past. This number is 20% of all the galaxies in the correct magnitude range in the part of the sky surveyed; it is likely to be a severe underestimate of the total number of binaries which have merged in the past both because of the stringency of the sample selection criteria and because the initial distribution of separations may have been more strongly peaked at small radii than the distribution implicitly assumed above. We estimate that these effects could increase the percentage of merged binaries by a factor between two and five.

If one is unwilling to accept that most of Turner's pairs will merge during their next orbital period, one can ask how small their haloes need to be to avoid strong tidal interactions. The mean projected separation of the 59 pairs in the sample is 79 kpc. Under the assumption that the distribution of pair separations is a power law and is independent of the magnitudes of the constituent galaxies, the correction factor from mean projected separation to mean true separation is easily calculated. For all pairs with given magnitudes at a given distance,

$$\frac{\bar{r}_p}{r} = \frac{\int_0^\infty \int_0^{\pi/2} dr d\theta \sin\theta f(r \sin\theta, D) n(r) r \sin\theta}{\int_0^\infty \int_0^{\pi/2} dr d\theta \sin\theta f(r \sin\theta, D) n(r) r}$$

where θ is the angle between the separation vector and the line of sight, $n(r)$ is the distribution of separations, and $f(r \sin\theta, D)$ is the probability of inclusion as a function of projected separation at distance D . If $n(r) \propto r^{-\gamma}$ each integral can be separated into

an integral over $r \sin \theta$ which cancels out of the fraction, and an integral over θ which remains to give

$$\frac{\bar{r}_p}{\bar{r}} = \frac{\int_0^{\pi/2} d\theta \sin^\gamma \theta}{\int_0^{\pi/2} d\theta \sin^\gamma \theta} \quad (1)$$

This result can be expressed in terms of Γ -functions for all $\gamma > 0$. Since equation (1) does not involve D it holds for the sample as a whole, and the correction factor is independent of whether the averages are number or luminosity weighted. Turner obtains $\gamma = \frac{1}{2}$ for his sample, giving $\bar{r}_p/\bar{r} = 0.46$; the mean true separation of his pairs is, therefore, 173 kpc, and if they are not to be strongly interacting we require $r_i < 58$ kpc on average for the haloes of the constituent galaxies. This limit must be reduced if the orbits are sensibly eccentric since the condition for merging applies to the distance of closest approach, whereas most of the pairs will be seen near apocentre.

Although the above arguments are crude, they demonstrate that while certain dynamical considerations seem to require massive haloes, there are others which can severely constrain them.

We thank Jerry Ostriker, Martin Rees and Ed Turner for helpful discussions.

Surface area and secondary nucleation theory

PRIMARY nucleation theory involves estimating the maximum free energy necessary to form a crystal of sufficient size so that further crystallisation results in a decrease in free energy. This free energy increase is caused by the creation of surfaces with the liquid or vapour. (The number of sides will depend on crystal symmetry and crystal habit. Here we will consider only the simplest six-sided crystal.) After a crystal of this minimum size has been formed it is often necessary to consider a secondary nucleation process which involves the maximum free energy necessary to crystallise a new layer on one of the existing flat crystal surfaces. This note reports an error in the estimation of surface area in the theory of secondary nucleation processes. This error makes little difference when applied to the crystallisation of small molecules but it can have significant results in the crystallisation of polymer molecules.

The secondary nucleation process controls the growth rate even after the primary crystal has grown macroscopically large. Again the cause of this free energy increase is assumed to be the creation of new surfaces between the crystal and the liquid (or vapour). It has become traditional in such nucleation processes to count only four of the five surfaces which such a secondary nucleus has exposed to the liquid. The argument being that the fifth surface simply replaces an equivalent surface on the parent crystal and

Fig. 1 Illustration of the four nucleation processes. Primary nucleation controls the number of crystals. Secondary nucleation controls the crystal growth rate. In polymer crystallisation tertiary nucleation controls the molecular fractionation process and quaternary nucleation may influence the morphology. In all of these processes the free energy of the nucleus is influenced not only by the surface energies but also by the change in conformational entropy of any attached cilia.

thus does not contribute to the increase in the total free energy. But the parent crystal may now be so large that any increase in the surface area of a secondary nucleus is insignificant in relation to the total free energy. The total free energy change reaches its maximum value at the critical size for the primary nucleus. It is not the change in total free energy which is important in secondary nucleation but rather the change in the free energy of the secondary nucleus considered as a small thermodynamic system¹ which controls secondary nucleation. A small thermodynamic system is one whose extensive properties (such as its free energy) may not be considered to be precise linear homogeneous functions of the thermodynamic variables. In such a system the surfaces have a dominant role in determining the free energy and one must consider all the surfaces which the small thermodynamic system makes with its surroundings. A coherent 'surface' which a secondary nucleus makes with the parent crystal may be considered to have zero surface energy but all surfaces which the nucleus makes with the liquid (or vapour) will contribute to the thermodynamic properties of the nucleus.

This distinction is not important when the crystallising entity is an atom or small molecule, since the secondary nucleus will always be one molecule in thickness, (or even if it is not, no difference in morphology can be distinguished) and the values of the surface energy derived from the kinetics of crystallisation have little intrinsic use except for comparison with other similarly derived data. But in considering the crystallisation of polymer molecules, the neglect of this fifth surface has led to the conclusion that such molecules should also crystallise in a monolayer of regularly folded chains^{2–4}.

Table 1 Number of crystal faces (six-sided crystal)

	Classical	Small system
Primary nucleation	6	6
Secondary nucleation	4	5
Tertiary nucleation	2	4
Quaternary nucleation	0	3

Although this assumption has led to reasonable results³ in explaining crystal growth kinetics and chain fold lengths, there are some experimental results which are incompatible. For example, large extended chain polyethylene crystals with very obvious striations parallel to the chain direction which should provide ideal secondary nuclei have been shown⁶ to be ineffective in promoting crystal growth when exposed to molten polyethylene substantially below its melting temperature. Furthermore, when the temperature is lowered sufficiently to allow crystallisation to proceed it does so by chain folding rather than extending along the existing secondary nucleation sites. These results can be explained by including all surfaces which a crystallising molecule makes with the liquid in the estimation of its free energy change⁷. Table 1 summarises the number of surfaces for each type of nucleation for both the classical and the small system approach.

Since tertiary nucleation and quaternary nucleation produce no detectable changes in atomic or small molecular crystallisation they need only be considered in polymer crystallisation where they are important in controlling morphology and molecular fractionation. In addition, in polymer crystallisation one may have surfaces exposed to the liquid which have attached portions of uncrystallised molecules. These attached molecules (sometimes called cilia) make important differences in the conformational entropy change and when added to the surface energies of the various nucleation processes make up the molecular nucleation process suggested by Wunderlich⁸.

The principal difference in applying this small system thermodynamic approach is the conclusion that secondary nucleation of polymer molecules need not result in a monolayer of regularly folded chain crystals but more likely will produce a multi-layer nucleus in which each molecule is folded into a more compact bundle with a random arrangement of folds.

Crystal structure of alinite

ALITE, a major constituent¹ of Portland cement, is essentially tricalcium silicate $\text{Ca}_3(\text{SiO}_4)\text{O}$, which contains both $(\text{SiO}_4)^{4-}$ and free O^{2-} ions^{2,3}. It is of interest to cement technology to examine how chloride contamination of the raw materials affects the phases present in the resulting cement, and the extent to which the free oxide ions of tricalcium silicate are replaceable by Cl^- . While this replacement can be regarded as complete in the compound^{4,5} $\text{Ca}_3\text{SiO}_4\text{Cl}_2$, it is only partially accomplished in the new compound alinite, which is described in this note.

Single crystals of the new compound alinite were obtained from cement clinker containing additional Mg, Al and Cl. The crystals have diffraction symmetry $I4/mmm$, with $a = 10.4714$ and $c = 8.6171$ (16) Å. In the completed structure, in the space group $I4_2m$ (no. 121), with $R = 0.034$, based on 401 independent reflections, the unit cell contains two structural units of ideal formula $\text{Ca}_{11}(\text{Si}_{0.75}, \text{Al}_{0.25})_4\text{O}_{18}\text{Cl}$. The structure exhibits

isolated aluminosilicate tetrahedra within a framework consisting of three distinct types of Ca coordination polyhedra.

Intensity data ($\sin^2\theta \leq 0.28$) was obtained with an Enraf-Nonius CAD-4 diffractometer and $\text{MoK}\alpha$ radiation. Solution of the three-dimensional Patterson (vector) map by multiple superposition (the rhombus method⁶) yielded positions for five atoms, one of which was taken to be Si and assigned the f -curve for Si^{4+} , while the remainder were treated as Ca^{2+} . Three cycles of structure factor calculation (in $I4/mmm$) followed by the preparation of electron density maps not only revealed the positions of all of the remaining (oxygen) atoms, but also identified the

Fig. 1 The structure of alinite—general features. For clarity, representative Cl and O positions are indicated, but only as vertices of polyhedra. A, (001) projection, showing the three types of Ca coordination polyhedra and (Si, Al) tetrahedra. The smallest circles are (Si, Al) positions—● and ○ indicate $z \approx 0$ and $z \approx 0.5$ respectively. Intermediate ○ are Ca2. Intermediate ● represent overlapping pairs of Ca1 atoms ($z \approx 0.29$ and 0.71 at the cell edges; $z \approx 0.79$ and 0.21 elsewhere). The largest ● represent overlapping pairs of Ca3 atoms ($z = 0$ and 0.5). B, One layer of the structure parallel to (010) at $y \approx \frac{1}{4}$ showing pairs of face-sharing Ca1 octahedra and (Si, Al) tetrahedra—large and small circles represent Ca1 and (Si, Al) atoms respectively.

original atoms as 3 Ca, 1 Si and 1 Cl, completely independently of any analytical data. Block diagonal least squares refinement of atomic positions (throughout) with alternate refinement of occupancies and B_{150} led to $R = 0.09$. The space group $I\bar{4}2m$, however, at a similar stage of refinement gave $R = 0.08$, and finally after refinement of anisotropic temperature factors $R = 0.034$. The final parameters are given in Table 1.

Although the completed structure indicates the contents of the unit-cell as $\text{Ca}_{11}\text{Si}_4\text{O}_{18}\text{Cl}$, charge balance requires partial occupancy of the Si position by Al ($\text{Si}_{0.75}$, $\text{Al}_{0.25}$), to give the overall composition given above. The conditions in which the phase is obtained, and preliminary analytical data support this contention.

The most frequently occurring Ca coordination is that of Cal. For example, indicated by i in Fig. 1A, Cal (at 0.0, 0.26, 0.29) has as nearest neighbours: Cl(0,0, $\frac{1}{2}$); O1(0.13, 0.32, 0.49); O1' (-0.13, 0.32, 0.51); O2(0.14, 0.14, 0.16); O3(-0.15, 0.15, 0.15) and O4(0, $\frac{1}{2}$, $\frac{1}{2}$). Each such octahedron shares its Cl-O1-O1' face with a second similar octahedron, related to the first by a two-fold axis passing through the Cl atom and the mid-point of the common O1-O1' edge ((i)—Fig. 1B). Such pairs of Cal octahedra occur in four-fold clusters (eight octahedra in all) round the 0,0,z lattice row, sharing Cl-O2 and Cl-O3 edges. The O2 and O3 vertices of two such clusters provide the cubic coordination of Ca2 ((ii)—Fig. 1A). The Cal octahedron pair units are also further associated in pairs (four octahedra in all) centred on the 0, $\frac{1}{2}$, z lattice rows. In this case the O4(0, $\frac{1}{2}$, $\frac{1}{2}$) and O4'(0, $\frac{1}{2}$, $\frac{1}{2}$) common to both Cal octahedron pairs, together with the two shared O1-O1' edges (one from each pair) complete the octahedral coordination of Ca3(0, $\frac{1}{2}$, $\frac{1}{2}$) ((iii)—Fig. 1A). A similar arrangement of four Cal octahedra, but with the octahedron pair interaction at right angles to that given immediately above applies to Ca3 at 0, $\frac{1}{2}$, 0. Figure 1A and B also indicates the distribution of the alumino-silicate tetrahedra.

The nature of metastable phases of carbon

THE following forms of carbon are already known: rhombohedral and hexagonal graphite, diamond, lonsdailite, carbines, Ries crater carbon, and metallic carbon. We describe here new metastable phases in the carbon system^{1,2} which we detected while sintering highly dispersed diamond powders. Similar structures were also observed during explosive transformations of pyrographite³ and in natural diamonds⁴ that had undergone shock metamorphism. In all cases, the observed structures are close to those of the Ries crater carbon⁵.

Under pressures > 600 kbar, carbon passes into the metal phase (C3)^{6,7}. When sintering diamond powders, it may be shown that the pressures set up between particles within the

contact interaction zone, substantially exceed the mean hydrostatic pressures.

By using the Hertz solution on the interaction of two balls², it is possible to find the radius of the zone of contact of two balls⁸ (that approximate the diamond grains) of radius R

$$a = \left(\mathcal{F}_1 \frac{\mathcal{D}R}{2} \right)^{1/3} \quad (1)$$

where

$$\mathcal{D} = \frac{3}{2} \left(\frac{1 - \sigma^2}{E} \right)$$

Here \mathcal{F}_1 is the mean force applied to one sphere, σ is the Poisson coefficient, E is the Young modulus. The mean pressure set up on the area does not depend on the particle radius and is equal to

$$P = P_0^{1/3} \left(\frac{2}{\pi \mathcal{D}} \right)^{2/3} \quad (2)$$

where P_0 is the mean pressure applied to the chamber in sintering. In the case of diamond $\mathcal{D} \approx 1.5 \times 10^{-7} \text{ bar}^{-1}$, if we assume $E = 9.5 \cdot 10^{12} \text{ dyn cm}^{-2}$, $\sigma = 0.25$ (ref. 9). Then,

$$P = 2.7 \times 10^4 P_0^{1/3} \quad (3)$$

Thus, if the pressure is applied such that $P_0 = 30 \text{ kbar}$, the mean pressure within the contact zone will exceed 800 kbar. Therefore, when sintering the diamond powders, the appearance

Table 1 Calculation of interplanar spacing (d) of the sintered diamond powder

Starting $d(\text{\AA})$	600 °C $d(\text{\AA})$	800 °C $d(\text{\AA})$	Notes
3.326	3.43	3.338	Graphite
3.010	3.06	—	Ries carbon
—	2.29	—	Ries carbon
—	2.12	—	Graphite
2.045	2.07	2.062	Diamond
1.965	—	—	Lonsdailite
—	1.52	—	Lonsdailite
1.291	—	—	Ries carbon
1.258	1.27	1.27	Diamond
1.234	—	1.23	Graphite
1.074	1.08	1.078	Diamond
0.900	0.894	0.894	Diamond
0.818	0.818	0.820	Diamond

of metallic carbon may be expected. As the metallic carbon may prove to be a metastable phase, it can pass into other forms of carbon. The additional phases that are observed in sintering diamond powders may turn out to be intermediate states between the metallic carbon, on one side, and the diamond and graphite, on the other. With this in mind, an experiment was carried out, in which the diamond powder having the mean radius of particles of about 2 μm was subjected to compression at the mean pressure of 59 kbar and the temperature of 1,200 °C. Then the diamond powder was annealed in a hydrogen medium at temperatures of 600 °C and 800 °C for 1 h. The initial and the annealed powder were subjected to X-ray examination, according to the Debye method. The examination results are presented in Table 1.

From Table 1, it seems that many interplanar spacings (d) are recorded in the initial powder, this may be attributed to different forms of carbon. In annealing, the system passes to a state where only diamond and graphite are present.

Table 2 Results from the pulse-heated diamond powder

Intensity (relative units)	<i>d</i> (Å)	<i>d</i> diamond (Å)	Note
100	2.05	2.06	
10	1.746		β-carbine (1.750)
5	1.523		β-carbine (1.550)
80	1.260	1.261	
70	1.073	1.075	
60	0.891	0.892	
70	0.818	0.818	

In the case of the pulse radiant heating of the diamond powder up to 2,000 °C and its rapid cooling (which obviates the annealing of metastable states), additional phases also appear, as shown by Table 2.

From Table 2, it seems that the carbines should occupy the intermediate place between diamond and graphite.

One possibility is that, aside from the known crystallographic forms in the carbon system (like the boron nitride system), there exist transient metastable states whose stability is determined by the potential barrier height. Transition from one form of carbon to another may occur, either via those metastable states or, possibly, directly.

The following seems probable: the Ries crater carbon, which has formed on the place where a gigantic meteorite has fallen, is a product of the inverse transition of metallic carbon (or the phases that are close to it) into a state which is more stable under atmospheric pressure.

Etching on large single crystals of stearic acid

ETCHING is one of the most useful ways of directly observing dislocations in a crystal¹. Many studies have been made of dislocations in organic crystals, such as aromatic hydrocarbons², but no reports on the dislocations in fatty acid crystals have been published because no large single crystal could be obtained. Recently we have succeeded in obtaining large single crystals of the saturated fatty acid stearic acid from solutions of organic solvents³. We describe here attempts to etch single stearic acid crystals using organic solvents. Optical and transmission electron micrographs of etch pits reveal several novel features and give an apparent correlation between the pits and the dislocations in stearic acid crystals.

Crystals of stearic acid were grown from a solution in benzene; the average size was about 5 × 5 mm² in area and 1 mm thick. The crystal form was monoclinic (B-form)³. The long chain of the stearic acid molecule was directed towards the (001) direction.

Etch pits were optically observed on the as-grown (001), *ab*, surfaces (Fig. 1). Attempts to etch other crystal surfaces were

Fig. 1 Optical micrograph of etch pits. Each direction was determined by the X-ray analysis. Etching for 5 s in acetone at 18 °C. Scale bar, 30 μm.

unsuccessful. A variety of organic solvents were examined as etchants; acetic acid produced ill-defined patterns, while acetone, ethanol, benzene, carbon tetrachloride, and chloroform produced well defined etch pit patterns of lozenge shape. In every case, except for acetic acid, pits of about 10 × 10 μm² in area were easily produced within a few seconds at 18 °C all over the surface. As shown in Fig. 1, almost all the pits have a common crystallographic direction. The two angles of lozenge-shaped pits were 75° and 105°; the values were the same as those of the crystal habit. The density of the pits was of the order of 10⁴ cm⁻². Two types of pits can be seen from Fig. 1. One is of the inverted pyramidal shape, and the other is of the inverted truncated pyramidal shape.

Fig. 2 Electron micrographs of two typical pits. Etchant, acetone. The first stage of replica was made by shadowing at 30° with germanium and by supporting normally with carbon. *a*, Two adjacent pyramidal pits; *b*, a flat-bottomed pit. Scale bar, 2 μm.

Fig. 3 Optical photograph showing part of the whole cleaved crystal and a sketch of a cleaved crystal. The lower plate, not bent, was used for simultaneous observation. Scale bar, 1 mm.

Transmission electron micrographs around the centre of an etch pit give molecular features of the etching process in detail. As shown in Fig. 2a the pit has several spiral steps whose terminations can be distinguished clearly at the specific points on the pit. These spiral steps also indicate a possible singular centre of the dissolution. Thus the pyramidal pit takes its position at the emergent end of the dislocation perpendicular to the (001) plane. Similar dislocations in stearic acid crystals have already been predicted from the observation of growth spirals on the as-grown (001) surfaces¹. In Fig. 2b, the flat area, without any etching step, of the pit-bottom can be thought to be molecularly flat. The molecularly flat-bottomed pit can be interpreted by the movement of the dislocation during the etching process; if the dislocation moves out of a pit formed during the first etching, further etching must enlarge the pit in the lateral direction so that the initial pit becomes flat-bottomed. At the same time, the movement of the dislocation would produce a new pyramidal pit at the final position of the dislocation.

If a dislocation, penetrating through the crystal from one surface to another, does not move during the etching process, the pit in direct correlation to such dislocation would grow to be a deeper and larger pyramidal one, while the flat-bottomed pit becomes wider but not deeper, as the etching proceeds. The penetrating dislocation is expected to appear at the cleavage surface. To verify this, the etch pits on the as-grown surface as well as the cleavage surface, (001) plane, of a single crystal were observed simultaneously (Figs 3 and 4). Figure 4 shows the

Fig. 4 Optical micrographs of the etch pits of pyramidal shape, no. 1 and 2, and of flat-bottomed shape, no. 3 and 4. *a*, taken in focus on the as-grown surface. *b*, taken in focus on the cleaved surface. Etchant, acetone at 18 °C. Scale bar 100 μ m.

developments of the two types of pits during their etching process. Two pits of no. 3 and 4, with a rather small-flat bottom at the etching time of 5 s, become large typical flat-bottomed pits in 13 s after the start of etching. On the other hand, each pyramidal pit on the as-grown and cleavage surface becomes deeper and larger, and then each centre of the two pits approaches each other in the projected *ab* plane. This approach can be easily understood because the dislocation line is inclined to the direction of the illumination. Thus it is obvious that two pyramidal pits observed in Fig. 4 lie at the two ends of the dislocation penetrating through the crystal.

Can sunspots influence our weather?

THE discovery of sunspots, in particular the 11-yr cycle, has led to many attempts to detect correlations between the sunspot number and weather changes in the Earth's troposphere¹. The past decade has seen a renewed interest based on modern data and the concepts of solar-terrestrial physics².

Claims have been made about correlations between H α -flares, crossings of the solar magnetic sector boundaries or sunspots, and tropospheric effects such as low pressure troughs at the 500-mbar level³, the influx of stratospheric air masses⁴, thunderstorm activity⁵, geoelectric potential⁶ or rainfall⁷. There is no general agreement about the reality of these effects because it is difficult to prove their significance and no acceptable cause and event mechanism has been proposed. Many authors have considered the invisible part of the active Sun as a possible source of these effects because the electromagnetic and corpuscular components of the radiation from the active Sun generate spectacular disturbances in the atmosphere above 60 km. The energies involved in bringing these disturbances about, are only a minute fraction of the solar constant and are, therefore, unlikely to have any direct influence on the troposphere⁸.

King *et al.*⁹ have shown that during the last 11-yr solar cycle, the sunspots tended to appear on preferred longitudes on the Sun so that a period of about 27.5 d, the mean period of the solar rotation, is clearly visible in the sunspot number. This is in accord with observations of coronal transients¹⁰, high-speed solar wind flows¹¹ and the sector structure of the interplanetary magnetic field¹². King *et al.*⁹ claimed furthermore, that the solar rotation effect in sunspots is correlated with changes in the height of the tropospheric 500-mbar level. The global pressure field displays a wave-like pattern with waves of zonal wave numbers 0, 1 and 2 having maximum amplitudes at higher latitudes⁹.

Although this observation has not been confirmed it suggests a mechanism which may be associated with the visible spectrum of the solar radiation. Radiation from the active Sun, which behaves like a rotating beacon, may influence the transmission of the Earth's atmosphere so that the radiation reaching the ground varies with the same period of ~ 27 d. At least one piece of evidence indicates that the solar constant *S* observed on the ground exhibits such a periodicity with an amplitude of about 0.1% (ref. 13).

In order to estimate the reaction of the atmosphere to such a small variation of S , consider an isothermal atmosphere with scale height $H = 8$ km. The mean energy input per unit mass within the atmosphere due to a change $\Delta S = 10^{-3} (1-A) S \simeq 1 \text{ W m}^{-2}$ is given by

$$\Delta Q = \frac{\Delta S}{4\rho_0 H} = 2.3 \times 10^{-5} \text{ W kg}^{-1} \quad (1)$$

where $A = 0.3$ (the albedo), $\rho_0 = 1.3 \text{ kg m}^{-3}$ (the density at the ground) and $S = 1.37 \text{ kW m}^{-2}$ (the solar constant).

From the first law of thermodynamics and the hydrostatic law, I estimate a pressure amplitude of

$$|\Delta p| = \frac{\Delta S}{4\omega H} = 10 \text{ N m}^{-2} = 0.1 \text{ mbar} \quad (2)$$

if $\omega = 2\pi/27 \text{ d} = 2.7 \times 10^{-6} \text{ s}^{-1}$. The solar radiation primarily heats the ground, from where it is transported into the atmosphere through turbulent heat exchange. That transport mechanism is mainly effective within the lowest part of the troposphere so that ΔQ from equation (1) is probably an underestimation for that part of the atmosphere. The land-ocean coverage is such that global-scale waves including mainly those of zonal wave numbers 0, 1 and 2 are generated and propagate upwards. The prevailing, but fluctuating, westerly wind modifies the horizontal and vertical structure of the planetary waves, and it is clear that the only waves that will be detectable within the meteorological noise by a statistical analysis are those which have vertical wave lengths of the order of, or greater than, the scale height. It can be shown that these waves are of the Rossby-Haurwitz type having maximum amplitudes at higher latitudes.

Detailed calculations (to be published elsewhere) assume a heat source distribution on the ground which reflects the land-ocean distribution¹⁴. The heat input into the atmosphere by turbulent transport was derived from a diffusion equation¹⁴. Linear tidal theory was then used¹⁵ to determine the meridional and the height structure of the individual wave modes in the presence of a constant prevailing westerly wind of the order 10 m s^{-1} . Only those wave modes were considered which have vertical wave lengths of the order or greater than one scale height. It was shown that for zonal wave number $m = 2$, these waves consist of eastward- and westward propagating waves of the Rossby-Haurwitz type. For waves of wavenumber $m = 1$, only westward propagating waves of that type exist, so that the waves of zonal wavenumber two probably will dominate. Maximum pressure amplitudes of $|\Delta p| = 0.3 \text{ mbar}$ near $\pm 60^\circ$ latitude and on the ground are predicted for waves of wavenumber two. Waves of such small amplitude are at the limit of detectability. But they may be found in analyses such as that carried out by King *et al.*⁹.

The mechanism suggested here may be the primary source of different types of Sun-weather relationship. If short-lived meteorological phenomena such as those associated with solar flares or sector boundary crossings are generated by active longitudes on the Sun, the 11-yr solar-cycle effects may be the result of an 11-yr variation of the amplitude of the 27-d forcing function.

Equatorial solar rotation and its relation to climatic changes

THE equatorial solar rotation speed, estimated from observations made over the past 10 years of the sunspot longitudinal motions over the solar disk, has shown a tendency to increase as relative sunspot numbers decreased. During these years, covering most of solar cycle no. 20 (1965-76), the magnitude of the solar rotation speed averaged annually showed a good inverse correlation with the annual relative sunspot numbers. I suggest here that this variation of the equatorial solar rotation speed may be responsible for the Earth's present unusual climatic conditions.

The highest speed was observed for 1976, when the observed sunspot activity was at its lowest since 1967, except for 1974, and was approximately equal to that estimated for the year 1643, just before the beginning of the Maunder Minimum (1645-1715), during which very few sunspots were reported. According to Eddy *et al.*¹, there is evidence that, during the Maunder Minimum, the speed of the equatorial solar rotation, averaged annually, was larger by 4% or more than that now observed². They have based this assumption on analysis of the sunspot observations made by Scheiner, Hevelius and others in the seventeenth century (see ref. 3 for details). Although the causal relationship between the degree of the development of solar activity and the pattern of this solar rotation speed was not known, their result suggested that, during the period when this solar activity was higher relative to the averaged one, this degree of development, as indicated by the relative sunspot numbers, for instance, must be lower than that observed for any other period when this speed is relatively low². Furthermore, from their results, it could be predicted that the severe climatic conditions experienced during the Maunder Minimum might have been related to the strong depression of solar activity and hence with the increase of the solar rotation speed.

Based on observations of the motion of sunspot groups over the solar disk, Howard⁴ has measured the yearly variation of the mean speed of the solar rotation as a

Fig. 1 The relative sunspot numbers R since 1952. These numbers, often called the Wolf numbers R , are published annually by the Zurich observatory, based on the reports on sunspot numbers from observatories throughout the world. These numbers are counted by using the formula, $R = k(10g + f)$, where k , g and f are, respectively, the seeing factor, the numbers of sunspot groups and of individual sunspots. A curve predicting these numbers for the cycle no. 21 is indicated by a dotted line (see text). A heavy line shows the general trend of the sunspot activity for the three cycles nos 19-21.

function of the solar latitude for 1967–76. He found that this speed has gradually increased throughout this period until 1976, when the sunspot activity was at minimum. Furthermore, it should be noted that the speeds observed during the above period were all relatively greater than those estimated by Ward² for the earlier period.

Although it is not clear whether this tendency will continue for the coming cycle no. 21, it seems likely that the whole pattern will still show the same tendency as observed in the last cycle no. 20 (1965–76), even though it might slow down slightly during the rising portion of this cycle (1977–79). As suggested in Fig. 1, the relative sunspot number for the next maximum is expected to be 20 or so less than that observed in the last cycle, because the solar activity as a whole has tended to decrease since cycle no. 19 as predicted from both the observed progression of the 80-year quasi-periodic variation of the relative sunspot numbers and the relatively slower start of the present cycle no. 21.

In order to discover whether there is a causal relationship between the sunspot activity and the solar rotation speed, the values of this speed at the equator observed by Howard⁴ have been plotted as a function of the relative sunspot numbers for the years from 1967 to 1976. Figure 2 clearly shows that the magnitude of this equatorial rotation speed has an inverse relationship with these sunspot numbers. Thus, the solar activity as a whole tends to decrease with the increase of the speed of the equatorial solar rotation during the above period.

Fig. 2 The equatorial angular velocity A of the solar rotation as a function of the relative sunspot numbers R for the years from 1967 to 1976 (●, average velocity). (The data are from ref. 4.) E with error bar shows the velocity for 1643, two years before the beginning of the Maunder Minimum¹.

If the sunspot numbers during cycle no. 21 vary as predicted in Fig. 1, the tendency shown in Fig. 2 would continue for this cycle because of the lower sunspot activity; that is, it is possible that this speed will increase to the values observed during the Maunder Minimum.

In Fig. 2, the equatorial rotation speed for 1643, estimated by Eddy *et al.*¹, is also plotted as a comparison with the present trend. By examining the observed speed for 1643, the range of this speed has been estimated and shown with an error bar in Fig. 2. The mean value of this speed is almost the same as that observed in 1976, though the relative sunspot numbers are slightly different. Hence, it seems possible that the general trend of the variation of the equatorial rotation speed will be maintained during the new cycle if the relative sunspot numbers for these years behave as predicted in Fig. 1.

Climatic conditions were very severe during the Maunder Minimum as recorded in London, for instance^{3,5}. When the observations from this period are compared with the corresponding climatic conditions, it becomes possible to conclude that the rare severe depression of the solar activity (and the consequent speeding up of the equatorial solar rotation) was responsible for this little ice age for 70 years or more⁶.

Figures 1 and 2 and the discussion on the Maunder Minimum, indicate that the Earth's present unusual climate might be associated with the decreasing trend of the sunspot activity (Fig. 1) and the related increase in the equatorial solar rotation speed—the speed at the equator of the solar differential rotation. It therefore seems likely that the present unusual climatic conditions will remain as long as the solar activity continues to decrease.

When we consider both the photospheric magnetic field and the high-speed flow of the solar wind during the past few years, it is clear that both the large-scale coronal hole and the apparent width of this high-speed flow region have been steadily growing^{6,7}. Their steady growth strongly indicates that the decrease of the solar activity is likely to continue for the coming cycles, continued observations would give us important clues as to the Earth's future, in particular, to its climate. It may also be possible to study possible causal relationship between the Earth's climate and the solar activity variations in the long term.

Reproductive effort and life history strategy of the Aldabran giant tortoise

THE Aldabra giant tortoise, *Geochelone gigantea* Schweigger, has a large body size (19–120 kg)¹, long life span (65–90 yr)², late maturity (females 17–23 yr)^{3,4} and iteroparity³. The three isolated island populations of different densities on Aldabra show dissimilarity in their reproductive parameters (for example mean clutch size, mean egg weight, proportion of mature females breeding and the number of clutches per female per year) and in the variation of these parameters from year to year through annual changes in rainfall³. Moreover, their reproductive response to these changes in rainfall is rapid; they have a relatively high maximum (potential) rate of natural increase (maximum clutch size 28)³ and mature females in the high density population are half the weight of those in the low density area^{2,4}. I have postulated that the reproductive effort would differ between the different density populations and that this effort would change in relation to changes in food availability. This contention is supported by the results reported here.

I examine here the apportionment of the assimilated resources towards reproduction, growth and respiration and the selective pressures which give rise to this allocation of energy. Assimilation (A) is defined as the sum of production due to reproduction (P_r), production due to growth (P_g) and respiration (R). After the onset of sexual maturity, growth is very slow (ref. 2 and my unpublished results) and for the purposes of this work is taken to be zero. Thus $P_r/A \approx P_r/(R + P_r)$ and this ratio will be used to measure reproductive effort.

Table 1 Reproductive effort compared with population density and years

	Very low density (5 per ha)* 1976	Low density (7 per ha)* 1975	High density (27 per ha)* 1975	1976
Mean weight of mature female (g)†	48,300	46,700	19,300	
Reproductive output (g per ♀ per yr)‡	4,204	2,303	91	303
Reproductive output (kJ per ♀ per yr) §	29,786	16,317	645	2,147
Annual respiration (kJ per ♀ per yr) ¶	470,323	455,905	201,864	
Reproductive effort (%)	6.0	3.4	0.3	1.0

*Figures taken from ref. 1.

†Maturity was determined by dissection³.‡Mean clutch size × mean egg weight × mean clutches per ♀ per yr³.

§Calculated using energy value per g dry weight of eggs excluding the shell (my work with N. K. Jenkins, in preparation).

¶Assuming 7 h activity (feeding) and 17 h inactivity (sleeping) per 24 h (from observation) (my unpublished results). Oxygen consumption in ml per animal per h (ref. 11) is 140.8 (individual weight^{0.97}) for active animals and 45.47 (individual weight^{0.82}) for inactive animals. Calorific equivalent for 1 ml of oxygen is 5.05 where respiratory quotient is unity¹¹.

||Mean reproductive output/(mean reproductive output + mean annual respiration).

This index is subject to several objections as it does not take into account the energy expended in growth in the annual energy budget (albeit low), finding or digging a suitable place for egg deposition, possible differences in metabolic rates between individuals from the three populations or possible variations in the energy costs of egg production. The care invested in a single offspring was estimated by the average egg weight as there is no parental care after oviposition. Recognising these difficulties, I feel that the methodology is adequate to allow discussion of the differences in reproductive effort and the life history adaptations of this large terrestrial herbivore.

Table 1 shows the reproductive effort compared with population density during the 2 yr of study. Reproductive effort increased as the population density decreased. The rainfall increased by approximately 40% in 1976 compared with 1975 and there was a greater proportional increase in reproductive effort in the high density population than in the low density population through an increase in food resource availability.

One would not expect any increase in reproductive effort by the low density population if it was food resource limited. But both the very low density and low density populations are expanding^{1,3}. The apparently greater sensitivity of the high density population to changes in food resource availability (as represented by rainfall) suggests they are closer to the carrying capacity (that is available food) than in the low density population. The low density population is mainly limited, probably much below the level set by food availability, by high levels of nest destruction by nesting females caused by the severe lack of suitable nesting areas³. Indeed the increase in reproductive effort by the low density area females occurred through increasing mean egg weight, whereas in the high density area mean clutch size, mean egg weight and the proportion of mature females breeding all increased (ref. 3 and my work with M. Coe, in preparation). This was the only available 'tactic' left to the low density area females in order to increase their effort, as any increase in nest numbers would involve the destruction of an equivalent number of existing nests and an increase in clutch size would have a similar effect. In both years of study the number of nests remained the same³.

In the high density population mortality is caused mainly by thermal stress¹. Individual tortoises must spend the middle of each day (approximately 1000–1600 h) shading⁴ and, as the distance between shade points particularly on the coast (with a high density population during the rains (ref. 4 and my unpublished results)) prohibits movement by exposing the animal to probable death, their feeding activities are confined to a specific area. Only during short (2–3 d) and infrequent periods of dull cloudy weather can the tortoise move more freely. When the Sun abruptly returns after these periods large numbers of recently dead animals are found well away from any available shade (my unpublished results). It can be predicted that as the rainy season gives way to the dry season (with far fewer dull weather periods) food availability will decrease. Eventually the local population within these shade-focussed feeding areas must exceed the food availability and it is at this time of year that tortoises will move away from these areas in large numbers, presumably risking death through thermal stress rather than slow but inevitable malnutrition. This, mainly circum-

stantial, argument together with other observations on reduced body size^{1,2}, retarded growth^{2,3}, very low recruitment³, pre-ovulatory follicular atresia³ and the ratio of estimated to predicted production⁵ supports the suggestion that the population in the high density area is at the carrying capacity determined by food.

The low density population is in a relatively less food-limited environment and shows early maturity and large clutches of large eggs; whereas the high density population, living in a more food-limited environment, shows delayed maturity and small clutches of small eggs. Most of these parameters could be predicted if the position of the populations with respect to resources were the primary determinants of the evolution of life history characters. The advent of large eggs in the low density population, however, was not predicted as the eggs in the very low density and high density populations were both small³. Large eggs produce large hatchlings which survive better than small hatchlings³. Giant tortoise hatchlings for the first 2 or 3 yr of life feed in areas where, because of the terrain, animals older than 4–5 yr cannot feed (my unpublished results). It was argued³ that these very young individuals had greater difficulty in finding suitable food in the low density area than in the other two areas and therefore the larger eggs were incorporated into the life history adaptation. Evidence for this hypothesis was inferred from observing that hatchlings in the high density area grew more than those in the low density area during the first year³.

It becomes apparent when considering the high maximum rate of natural increase, the quick response to changes in food availability, the larger hatchlings in the less-limited low density area and the lower mean weight of mature adults in the high density area that the Aldabran giant tortoise populations highlight the inadequate and over-simple concept of *r* and *K* selection⁶. The low mean weight of mature females in the high density area together with the ability to make a rapid and potentially large increase in reproduction may have been selected in order to effect a compromise between parental risk (in making resources available to the offspring) and food availability. By having a smaller body size, a greater proportion of any increase in food availability can be used in reproduction without increasing, unacceptably, the risk to a parent's lifetime reproductive success.

A recent paper⁷ on the problem of 'temporally dynamic reproductive strategies' viewed in terms of the conceptual framework of *r* and *K* selection concluded that mean *r*-*K* continuum⁸ positions have relatively little explanatory value where a measure of year-to-year variation in reproductive effort is more relevant in considering life history strategies and selective pressures. Moreover it was suggested that the proportion of mature females breeding can be used to infer variation in population reproductive effort. In the case of the giant tortoise the increase in reproductive effort in the low density population would be overlooked using this index because it occurred through an increase in mean egg weight and not an increase in breeding females. Additionally in the high density population not only did the proportion of mature females breeding increase but mean clutch size and mean egg weight also increased. Other work^{9,10} has emphasised the need to consider the environmental dimensions essential to provide complete understanding of the evolution of life histories. It is hoped that this

example within a species clearly demonstrates some of these dimensions.

Behaviour of adult and immature male baboons during inter-group encounters

SOCIAL interaction between groups of Old World monkeys varies from peaceful mingling to marked aggression¹⁻³. One constant feature, however, concerns the differing behaviour of immature and adult males; and these differences have been related to differences in male reproductive success at different stages of the life cycle. Immature and young adult males in multi-male groups of baboons and macaques frequently approach and interact with individuals outside their natal group, sometimes transferring from one group to another⁴⁻⁷. Two suggested causes of such group transfer are inability to gain access to oestrous females in the natal group and attraction to oestrous females in other groups⁸. In contrast, adult males—both in species with one-male social units and in species with multi-male groups—are frequently aggressive during intergroup encounters, often chasing or 'herding' members of their own group away from other groups^{7,9,10}. Herding usually involves high-ranking adult males who are also the individuals who copulate most often^{10,11}. Males are most likely to herd adult females, but rarely herd females who are lactating¹⁰⁻¹². (Although occasional herding in gelada baboon one-male units has been reported¹³) Herding has been suggested both to mobilise individuals before group movement⁷ and to maintain a male's access to oestrous females over time¹⁰. To investigate the function of herding we observed the intergroup encounters of one multi-male group of baboons for 15 months. Our observations suggest not only that herding is correlated with differences in male reproductive success but also that it is related to changes in the female reproductive cycle and to long-term bonds between particular males and females.

We studied the intergroup encounters of a group of southern African baboons (*Papio cynocephalus ursinus*) consisting of two adult males, eight adult females, and between 14 and 20 immatures. During 15 months' observation, this group came to within 500 m of another group on 174 occasions, with such 'encounters' lasting from 15 min to 16 h (the latter occurred when two groups occupied adjacent sleeping sites). Although the study group regularly came into contact with three different groups, and behaved similarly during encounters with each, 77% of all encounters involved one group of approximately 50 individuals.

During 44% (77) of all encounters, one or more of the group's five subadult males (estimated age 44-58 months)

sat at the boundary between groups. In addition, during the 4 months preceding their emigration, at least one of the subadults exchanged affiliative gestures with the other group's subadult males and/or copulated with the other group's females on 59% (13) of all encounters. Copulation occurred when oestrous females from the neighbouring group approached the study group and presented to both adult and immature males. Although the females were occasionally herded away by the adult males of their group, such males never threatened males in the study group^{10,14}. More often, males in the study group were able to respond to the females' presents. Immature males and the subordinate adult male were more likely than the alpha male to receive presents, and subadult males were the most likely to respond to them (Table 1). When four of the subadult males emigrated from the study group, they did so following an encounter which included copulations, and they left in the company of oestrous females from the neighbouring group.

Concurrently, more than 90% (159) of all encounters were accompanied by at least one 'bout' of herding by an adult male: separate bouts were defined as any instance of herding separated by an interval of at least 1 min when herding did not occur. The alpha male, who accounted for the largest single proportion of copulations¹⁵ and fertilised six of the eight females who became pregnant¹⁶, was responsible for 85% of all herding bouts. Immature males, in contrast, accounted for less than 1% of all observed herding bouts.

Table 1 Proportion of presents by oestrous females from neighbouring groups to which males responded, either by touching, grooming, or copulating with the presenting female

		No. of presents received	% Presents responded to
Adult ♂♂	Alpha	0	—
	subordinate	20	10
Subadult ♂♂	A	10	40
	C	8	50
	K	4	50
	S	3	67
	L	17	59

During herding, the male involved chased one or more female around and through the group, repeatedly giving loud double-barks^{10,17}. Of 200 herding bouts, 81% (161) began with the chasing of one adult female. During the course of herding, however, other animals were often supplanted by the male's approach and they, too, could be herded. Herding seemed to cause great anxiety among females and immatures, who screamed, raised their tails, and fear-grinned as they were herded. The net effect of herding was to drive most adult females, and many immatures near them, away from the other group. Herding was therefore both an aggressive, disruptive behaviour and a behaviour which tended to promote intragroup cohesion by maintaining spatial separation between groups.

Throughout the study, there was a variable number of females each month either sexually cycling, pregnant, or lactating. Taking data from the 150 occasions when the alpha male 'chose' only one female for herding, Fig. 1 shows that this male herded sexually cycling females more often, and lactating females less often, than would have been expected had females been 'chosen' at random.

The amount of herding received by each female thus depended on both the ranging behaviour of her own and other groups, and her reproductive state when intergroup encounters occurred. It was also possible to test for individual preferences on the part of each adult male and to

Fig. 1 Proportion of all adult females who were either (a) sexually cycling, (b) pregnant or (c) lactating each month (broken lines), compared with the proportion of the alpha male's 'choices' for herding each month that involved females in each of these reproductive states (solid histograms). Sexually cycling females were chosen more often than expected in eight out of eight possible months, pregnant females more often in six out of 11 months, and lactating females more often in 2 out of 13 months

compare these preferences with the males' long-term bonds with particular adult females.

Examination of social interactions between the two adult males and eight adult females throughout the reproductive cycle indicated that, whereas each male formed sexual consortships with a number of females at the height of oestrus¹⁶, males and females also showed individual preferences which persisted during pregnancy and lactation¹⁸. Table 2 presents data on the relative frequency with which each adult male herded each female in different reproductive states. Results indicate that, in all reproductive states, males were most likely to herd females with whom they had the closest long-term social bonds. Each male's preference for one specific individual often overrode preference for females in particular reproductive states, as, for example, when the alpha male repeatedly herded his preferred partner even though she was lactating and there were other, sexually cycling females in the group.

Disparities in the behaviour of adult and immature males may be related to the males' differing access to oestrous females at different times during their life cycle. Adult males in the study group accounted for the great majority of copulations—particularly around the time of ovulation—

and seemed to limit the access of immature males to sexually receptive females¹⁵. As a result, immature males may have been more attracted than adult males to sexually receptive females in neighbouring groups.

The alpha male's 'choice' of particular females for herding had two important consequences. First, in both the short and the long term, it served potentially to increase his reproductive success by isolating from males in other groups (1) those females who were about to ovulate, and (2) those females in whom the male would invest the greatest direct social support in future. Male herding of sexually receptive females was therefore both behaviourally and functionally similar to the herding of oestrous females in intragroup interactions observed in a previous study of a multi-male group of baboons¹⁴. Second, male choice of particular females seemed to minimise the potentially disruptive effect of herding. As noted earlier, each male was most likely to herd the female with whom he had the closest long-term social bond. Consequently, herding most often involved those individuals who were most likely to follow agonistic behaviour with relaxed proximity or grooming¹⁸. Males therefore seemed to be able to maintain separation between groups with a minimum of social disruption.

Table 2 Ranked frequencies with which each female was 'chosen' for herding by each adult male in each reproductive state

♀	Alpha male (n = 150)				♀	Subordinate male (n = 11)			
	Sexually cycling	Pregnant	Lactating	Sum of ranks		Sexually cycling	Pregnant	Lactating	Sum of ranks
H	2	7	6.5	15.5	H	5	5.5	5.5	16.0
W	6.5	6	4	16.5	W*	1	1	1.5	3.5
L*	1	1	2	4.0	L	5	5.5	5.5	16.0
S	6.5	5	6.5	18.0	S	5	5.5	5.5	16.0
LP	6.5	4	3	13.5	LP	5	5.5	5.5	16.0
PM	4	8	1	13.0	PM	5	5.5	1.5	12.0
M	3	2	5	10.0	M	5	2	5.5	12.5
P	6.5	3	8	17.5	P	5	5.5	5.5	16.0

n, Number of herdings involving each male and one female.

*Each male's 'preferred' female^{16,18}.

Relative frequencies with which each female was chosen by each male in each reproductive state calculated as follows: for example, for the alpha male and female H during H's sexual cycle

$$\frac{\text{total times alpha male 'chose' } \text{♀H during } \text{♀H's sex. cyc.}}{\text{total times alpha male 'chose' any female during } \text{♀H's sex. cyc.}}$$

For every female, at least five bouts of herding occurred during each reproductive state.

Finally, the pattern of male herding reported here for a multi-male group of baboons bears several similarities to herding by hamadryas baboon males in one-male units¹⁰. Results thus support the suggestion^{10,11} that there may be marked similarities in the pattern of social relationships within one-male and multi-male social groups despite the more obvious differences in group size and composition.

We thank A. H. Harcourt, C. Packer, and especially Professor R. A. Hinde for advice and criticism during the preparation of this paper.

Nitrate reductase-deficient mutants in barley

MUTANTS have long been used to study genetic and biochemical regulation of metabolic pathways in microorganisms. Often it is a relatively simple task to screen large bacterial populations for an individual lacking a specific enzyme or enzyme product. Defined enzyme mutants would also be valuable research tools for plant geneticists and biochemists. Unfortunately, very few biochemically defined mutants have been selected in higher plants, principally because of the genetic and biochemical complexity, and the long generation time of higher plants¹. But, these obstacles could be overcome in plants by inducing high mutation frequencies and developing effective techniques for selecting biochemically defined mutants. High mutation frequencies can be readily induced in some higher plant species by sodium azide, a potent base substitution mutagen in barley^{2,3}. Nitrate reductase, which has an important function in higher plants⁴, has been extensively studied in bacteria and fungi⁵, is highly regulated^{6,7}, and has several catalytic activities including NAD(P)H, FMN₂ and reduced methyl viologen nitrate reductase activities, and NAD(P)H cytochrome *c* reductase activity⁸. Nitrate reductase is therefore an excellent enzyme in which defined mutants in higher plants can be selected, studied, and compared with microorganisms. We describe here a procedure for the induction and selection of nitrate reductase-deficient mutants in higher plants, and the partial characterisation of three nitrate reductase-deficient mutants in barley.

Nitrate reductase-deficient mutants were induced with sodium azide in 'Steptoe' barley (*Hordeum vulgare* L.) as described by Kleinhofs *et al.*^{9,10}. Steptoe barley seeds were hydrated at 0–2 °C overnight and then germinated at 20 °C in vigorously aerated water for 8 h. The seeds were then placed in an aerated solution containing 1 mM sodium azide and 0.1 M phosphate buffer (pH 3.0) for 2 h. The treated seeds were washed for 30 min, blotted and dried in a fume hood. The dry seeds were planted in an

isolated field plot. The crop produced (M₂ seed) was harvested in bulk.

The nitrate reductase-deficient mutants were selected from the M₂ segregating population by qualitatively estimating *in vivo* nitrate reductase activity. Individual 7-d-old control or segregating M₂ seedlings with normal green appearance were screened for the presence of nitrate reductase activity by using a modification of the *in vivo* assay described by Finke *et al.*⁹. Approximately 8 cm of the primary leaf was excised, cut in half, and placed in a test tube containing 4 ml of an incubation medium containing 0.1 M potassium nitrate, 0.1 M potassium phosphate (pH 7.0) and 0.01% Tergitol NPX. The leaf tissue was then vacuum infiltrated and incubated in the dark at 30 °C; nitrite was then determined as previously described⁹. Nitrate reductase-deficient seedlings were transplanted to soil and fertilised with ammonium sulphate.

Nine nitrate reductase-deficient seedlings were selected from approximately 6,000 M₂ seedlings tested. None of the 5,000 control seedlings tested was nitrate reductase-deficient. Five of the nine nitrate reductase-deficient selections were sterile or otherwise failed to produce seed. Progeny tests of the four selections confirmed that three (Az12, Az13, Az23) are nitrate reductase-deficient (Table 1).

These mutants have low *in vivo* nitrate reductase activity and low *in vitro* nitrate reductase activity when either NADH or FMN₂ is used as an electron donor. All three mutants are also similar in that they have elevated leaf nitrate levels and nitrite reductase activities. But they differ in that Az12 and Az23 have low cytochrome *c* reductase activities whereas Az13 has cytochrome *c* reductase activity similar to the control. Similar results were obtained with field grown plants except that the nitrate content of the leaves of the nitrate reductase mutant plants was much greater than in the control (Table 2). In spite of the low nitrate reductase activity, the mutant selections seem to be as vigorous as, and morphologically indistinguishable from, the control.

The higher levels of nitrate in the mutants is presumably the result of the lowered capacity of the mutants to reduce nitrate. The high levels of nitrite reductase in the mutants (Table 1) may be caused by the high levels of nitrate inducer, although the levels of nitrate in the control are well above those generally considered necessary to give optimum induction of nitrate reductase¹⁰. Alternatively, the mutants may have lower levels of reduced nitrogen available for the repression of nitrite reductase synthesis. Ammonium and other forms of reduced nitrogen have been reported to repress nitrate reductase synthesis⁶ and would be expected to have a similar effect on nitrate reductase.

The different levels of cytochrome *c* reductase activity in the mutants seems to be the result of different muta-

Table 1 Nitrate, nitrite, cytochrome *c* reductase activities, and nitrate content of 7-d-old nitrate reductase mutant and control seedlings

Selection	NRA			NiRA	CRA	NO ₃ ⁻
	NADH	FMN ₂	<i>in vivo</i>			
Az12	0.4	0.0	0.2	315	43	1,806
Az13	0.4	0.0	0.3	355	242	1,657
Az23	0.3	0.0	0.3	370	36	2,492
Control	27.2	28.8	4.8	197	194	1,246

Nitrate reductase (NRA) was assayed *in vitro* with NADH as electron donor (ref. 15), with FMN₂ (ref. 16) and assayed *in vivo* (ref. 9). Nitrite reductase (NiRA) and nitrate content were determined as in ref. 15 and cytochrome *c* reductase (CRA) as in ref. 12. Enzyme activities are expressed as $\mu\text{mol per g of fresh weight per h}$ and nitrate content as $\mu\text{g NO}_3^- \text{N per g fresh weight}$. Plants were grown in a growth chamber at 20 °C and continuous light for 7 d as described by Warner and Kleinhofs¹⁵.

Table 2 Nitrate, nitrite and cytochrome *c* reductase activities, and nitrate content of field grown (heading stage) nitrate reductase mutants and control plants

Selection	NRA		NiRA	CRA	NO ₃ ⁻
	NADH	<i>in vivo</i>			
Az12	0.3	0.8	604	114	1,007
Az13	0.4	1.6	625	288	1,135
Control	19.6	10.0	226	174	41

tional events. It has previously been reported that nitrate reductase also has cytochrome *c* reductase activity^{11,12}. These results suggest that Az12 and Az23 mutations inactivate or prevent the synthesis of the nitrate reductase enzyme including the cytochrome *c* reductase component whereas Az13 seems to have the cytochrome *c* reductase portion of the enzyme still functional. Wray and Filner¹² reported that the cytochrome *c* reductase associated with barley nitrate reductase is induced by nitrate whereas two other cytochrome *c* reductases are constitutive and not associated with nitrate reductase. When grown on an ammonium nitrogen source, Az12, Az13 and the control have very low levels of nitrate reductase and approximately the same cytochrome *c* reductase activities (Table 3).

Table 3 Induction of nitrate and cytochrome *c* reductase activities in 12-d-old nitrate reductase mutant and control seedlings

Selection	N source	NRA	CRA	NO ₃ ⁻
Az12	NO ₃ ⁻	0.3	29	2,506
	NH ₄ ⁺	0.0	40	13
Az13	NO ₃ ⁻	0.3	343	2,579
	NH ₄ ⁺	0.1	46	19
Control	NO ₃ ⁻	30.5	300	1,545
	NH ₄ ⁺	1.2	49	9

When induced with nitrate, Az13 and control seedlings have a nitrate-inducible cytochrome *c* reductase which is presumably associated with the nitrate reductase protein. Based on work with nitrate reductase mutants in *Aspergillus nidulans*¹³ and *Neurospora crassa*¹⁴, it may be possible to predict the nature of the barley nitrate reductase mutants. Mutations in the regulator loci in fungi^{11,12}, result in the loss of all of the nitrate reductase catalytic functions and of nitrite reductase as well. Since all of the barley nitrate reductase mutants contain nitrite reductase then these mutations seem not to be in the regulator locus unless nitrate and nitrite reductases are controlled by separate regulator loci in higher plants. Fungi nitrate reductase structural mutants generally have nitrite reductase activity and in some cases nitrate-inducible cytochrome *c* reductase activity^{11,12}. Therefore, Az12 and Az13 are probably nitrate reductase structural mutants since both mutants lack the nitrate reductase catalytic functions and have nitrite reductase activity.

In addition to mutations in the nitrate reductase structural and regulator loci, mutations in the loci controlling the molybdenum component of nitrate reductase also result in the loss of nitrate reductase activity¹⁵. In *Aspergillus* the molybdenum component mutants have nitrite reductase activity and either a constitutive or an inducible cytochrome *c* reductase activity¹⁴. The mutants having the inducible cytochrome *c* reductase usually have low levels of nitrate reductase similar to Az13 (Table 3). Therefore, Az13 may be either a nitrate reductase structural mutant or a molybdenum component mutant assuming the barley and *Aspergillus* systems are analogous. Whether these nitrate reductase mutants are in the structural protein for nitrate reductase or some other

locus is not known. More mutants and subsequent analyses are needed to adequately resolve this question.

The induction and selection of defined enzyme mutants such as the nitrate reductase mutants described, should be of considerable help in resolving genetic and biochemical control mechanisms of metabolic pathways in higher plants. Nitrate reductase has received considerable attention in the past 20 years but the work in higher plants has been severely handicapped by the lack of sufficient genetic diversity. Nitrate reductase-deficient mutants have previously been identified in *Arabidopsis thaliana*¹⁷ and now in barley. These mutants are an important first step for studying the genetic regulation of nitrate reductase in higher plants.

This investigation was supported in part by the Graduate School research funds from the US NIH Biomedical Sciences support grant and College of Agriculture Research Center, Washington State University.

Possible *in vitro* test for screening drugs for activity against *Babesia* and other blood protozoa

THE normal method of screening compounds for activity against *Babesia* infections of animals is based in the first instance on testing the compound in laboratory rats or mice infected with *B. rodhaini* using a regimen similar to that described for the testing of anti-malarial compounds¹. Most compounds screened against *B. rodhaini* in this way show no activity at all, therefore there would be justification for developing an *in vitro* test which would greatly reduce the time, cost and numbers of animals involved. We describe here such a test which is applicable to all species of *Babesia* and which exploits the finding that *Babesia* parasites readily incorporate hypoxanthine in an *in vitro* culture system².

The parasites used were *B. rodhaini*³ maintained in intact LACG mice, *B. divergens*⁴ and *B. major*⁵ maintained in splenectomised calves, and a *Babesia* sp. (probably *B. ovis*) recently isolated from Scotland⁶ and maintained in splenectomised sheep.

Blood from infected and similar non-infected animals was set up in a series of flasks containing culture medium and a test compound. Appropriate controls were included. Cultures were incubated for 1 h and ³H-hypoxanthine was then added to all flasks, which were incubated overnight. ³H-hypoxanthine incorporation was measured the next day by liquid scintillation counting⁷. The amount incorporated

by *Babesia* parasites was obtained by subtracting the count of non-infected blood from that of infected blood.

Various compounds were tested and those that were active against *Babesia* parasites inhibited the uptake of ^3H -hypoxanthine, whereas inactive compounds did not (Table 1). Any compound which reduced the uptake of ^3H -hypoxanthine by about 75% or more was considered to be active.

In addition to detecting active compounds, the test also indicated which drugs were most effective against particular species of parasite. Of the babesicides tested, Imidocarb and Amicarbalide were the most active *in vitro* against *B. rodhaini* and *B. divergens*, and Diminazene was the most active against *B. major* and '*B. ovis*'. These findings agree with *in vivo* studies (refs 8–10 and D. W. Brocklesby, personal communication). Diminazene, however, was ineffective *in vitro* against *B. rodhaini* and *B. divergens* at the concentration used, although in a subsequent experiment a tenfold increase in drug resulted in >95% reduction in ^3H -hypoxanthine uptake. This drug was also less effective *in vivo* against these parasites^{8,9}. *In vivo* studies with Trypan blue have shown that it is principally active against 'large' babesias¹¹ and ineffective against *B. ovis*¹⁰, *B. major*¹² and the small parasites; similar findings were recorded in the present work. The antimalarial drug, chloroquine sulphate, was ineffective *in vitro* against the three parasites screened; similar lack of activity was recorded *in vivo*¹³.

Hypoxanthine itself blocked the uptake of ^3H -hypoxanthine, and both 6- and 2-mercaptapurine (structural analogues of hypoxanthine) seemed to be active. *In vivo* tests with these two compounds showed that they delayed time to death in *B. rodhaini*-infected mice by about 14%

(our unpublished observations). Their activity is probably explained on the basis of competition with hypoxanthine for the enzyme hypoxanthine guanine phosphoribosyl transferase¹⁴. Activity of 6-thioguanine can be similarly explained. Occasionally more ^3H -hypoxanthine was incorporated by treated samples than by controls. This could be as a result of drug-induced changes, such as increased parasite or erythrocyte permeability, or because of increased parasite metabolism, but such factors have not so far been investigated.

A small amount of ^3H -hypoxanthine is incorporated by non-infected blood, principally by white cells. This amount is insignificant when compared with the massive uptake by *Babesia* parasites⁷. By subtracting counts of control blood from those of infected blood such 'background' was largely eliminated. Any difference in white cell count between control and infected blood, which might result in a possible difference in 'background', would not be detected by the present test. The counts can therefore be regarded as an accurate record of ^3H -hypoxanthine uptake by *Babesia* alone.

The level of parasitaemia, provided it was >5% and not past peak², did not seem to affect the percentage inhibition of ^3H -hypoxanthine uptake. For example, three trials with amicarbalide against *B. divergens*-infected blood of 12.5%, 18.5% and 24.0% parasitaemia gave the following respective figures for uptake of ^3H -hypoxanthine, 24.1%, 21.0% and 17.2%.

It is not yet clear how the test works, but a purine salvage pathway involving incorporation of hypoxanthine may be essential for nucleic acid synthesis in *Babesia*², just as in *Plasmodium*^{15–17}, in which case any compound which

*Figures followed by (2) or (3) indicate that values are the means of two or three separate readings. Each reading represents the mean from duplicate samples.

Blood from infected and control animals was collected into anticoagulant and washed thrice in PBS (pH 7.2). Aliquots of 6×10^8 erythrocytes were placed in 25-cm² Falcon flasks containing 10 ml of Eagles' MEM, supplemented with 100 IU ml⁻¹ of benzyl penicillin, 100 µg ml⁻¹ streptomycin sulphate, 25 U ml⁻¹ mycostatin, 50 mM HEPES buffer (pH 7.2) and 10% foetal calf serum. Appropriate drugs were added to cultures at the rate of 20 µg ml⁻¹. Cultures were incubated at 37 °C and after 1 h, 2 µCi of ^3H -hypoxanthine ml⁻¹ (specific activity 1.8 Ci mmol⁻¹) was added to each culture. Cultures were further incubated overnight; erythrocytes were collected after centrifugation at 1,500g and three washings in PBS. Cells were resuspended in 5 ml of PBS; 1-ml samples were transferred to 5 ml of 5% ice-cold TCA and duplicate 1-ml aliquots of this suspension were passed through separate 2.5-cm diameter 1.2-µm Millipore filters. Filter pads were washed and dried and then placed in scintillation vials containing 10 ml of toluene-based scintillation fluid. Counts per minute were recorded after 10 min of counting in a liquid scintillation analyser at 8 °C. Uptake of ^3H -hypoxanthine by parasites was recorded after counts were corrected to eliminate background and uptake by non-infected cells.

Table 2 Percentage uptake of ^3H -hypoxanthine by normal and Diminazene-resistant¹⁹ strains of *B. rodhaini* incubated *in vitro* in the presence of different babesicidal drugs

Strain of <i>B. rodhaini</i>	Control	Amicarbalide	Drug Quinuronium SO ₄	Imidocarb	Diminazene
Normal	100	17.3	28.2	14.6	39.5
Diminazene-resistant	100	11.6	32.9	5.0	77.9

Drug concentrations and experimental methods as for Table 1.

inhibits parasite multiplication, and thus nucleic acid synthesis either directly or indirectly, will result in a reduction of hypoxanthine uptake. The test may therefore be measuring the degree of drug-induced inhibition of nucleic acid synthesis. Although the mode of action needs to be determined, the test seems to be reliable, simple, quick and cheap, it does not involve the use of large numbers of animals; it can be applied to any species of *Babesia*; and the drugs do not require previous toxicity testing. Before *in vivo* tests, active compounds can be further screened at different concentrations *in vitro* and structure-activity relationships¹⁸ can be quickly evaluated.

Preliminary tests with a Diminazene-resistant strain of *B. rodhaini*¹⁹ suggest that drug resistance patterns may also be detected by the inhibition of ^3H -hypoxanthine uptake. The results shown in Table 2 agree with *in vivo* tests¹⁹ which have shown that a Diminazene-resistant strain was also resistant to Quinuronium sulphate but less resistant to Amicarbalide and Imidocarb.

In vitro tests for the detection of antimalarial drug activity, based on the inhibition of ^{32}P and ^3H -adenosine uptake by *Plasmodium*-infected blood, have been described^{20,21} but never widely adopted, possibly because of their complexity or lack of versatility. The test described here does not seem to be subject to these constraints and, since many malaria parasites are known to incorporate hypoxanthine^{15,16} readily, the test could also be considered for the primary screening of antimalarial drugs.

We thank Professor G. Urquhart, Drs R. E. Purnell and E. Beveridge for supplying parasite strains, Drs D. W. Brocklesby and D. L. Hughes for helpful discussions and Mr C. Mallinson for liquid scintillation analyses.

Synergistic interaction of testosterone and oestradiol inhibits spermatogenesis in rats

ONE experimental approach to male contraception has been the systemic administration of androgenic steroids, but treatment has failed sometimes to induce azoospermia¹⁻⁴. To overcome this difficulty, androgen-progestin formulations have been tested, but they did not inhibit spermatogenesis completely in all treated men⁵⁻⁸. We thought that this variable response was probably due to the relatively weak anti-gonadotropic activity of both androgens and progestins and the difficulty of controlling precisely the dose of steroids administered. We reasoned that azoospermia might be achieved in every male if steroids were administered continuously and at relatively constant rates and if progestins were replaced by a more potent inhibitor of pituitary gonadotropin secretion. We describe here the results of a test of the efficacy of testosterone-oestradiol formulations administered to adult male rats by means of a subdermal sustained release device. Oestradiol was used because, like testosterone, it is a naturally occurring steroid secreted by the mammalian testis⁹⁻¹³ and because it is a potent inhibitor of pituitary gonadotropin secretion¹⁴⁻¹⁶.

Ninety adult male Sprague-Dawley rats (225-260 g) were assigned randomly to one of 15 treatment groups. Subdermal implants of Silastic of different sizes, containing either testosterone or oestradiol-17 β were used to administer steroid. These sustained release devices were constructed from Silastic (polydimethylsiloxane) medical grade tubing because studies in our laboratory have established that such devices release hormonal steroids at relatively constant rates for a long time^{17,18}. Three groups of 30 rats each were given either no oestradiol-17 β or oestradiol-17 β -filled Silastic implants measuring 0.1 cm or 0.3 cm (release rate for oestradiol was approximately 0.1 $\mu\text{g cm}^{-1} \text{d}^{-1}$). The 30 rats in each group were further subdivided into five groups of six rats each, receiving either no testosterone or testosterone-filled Silastic implants measuring 1.0, 2.5, 4.0 or 6.0 cm (release rate for testosterone was approximately 30 $\mu\text{g cm}^{-1} \text{d}^{-1}$). The implants were prepared by filling Silastic tubing (Dow Corning No 602-305) with steroid and implanting it subdermally as before¹⁷⁻¹⁸. Three months later the rats were weighed and decapitated, trunk blood was collected and serum was prepared for radioimmunoassay of oestradiol¹⁹, testosterone²⁰ and luteinising hormone (LH)²¹. The seminal vesicles and ventral prostate were dissected, freed of extraneous tissue and weighed, the fluid was expressed from seminal vesicles before weighing. Spermatids and spermatozoa were counted haemocytometrically.

Table 1 Average number of spermatozoa and spermatids in adult male rats with subdermal implants containing testosterone or oestradiol

Oestradiol implant length (cm)	Testosterone implant length (cm)				
	0	1	2.5	4	6

from homogenates of testes from each animal²². Testicular perfusions were done as described earlier²³⁻²⁴.

Testosterone administered in the absence of oestradiol (Table 1) caused the expected biphasic changes in the combined number of spermatozoa and/or spermatids per testis²⁵. Numbers of spermatids and spermatozoa did not reach zero in any of the five treatment groups: this differs from the result reported by Berndtson *et al.*²⁵. The difference probably resulted because Berndtson *et al.* quantified spermatogenesis by counting germ cells in histological sections of testes²⁵, whereas we used a haemocytometer to count nuclei of spermatids and spermatozoa in a testicular homogenate. No significant alterations in spermatogenesis were apparent in rats receiving oestradiol without testosterone (Table 1). Surprisingly, testosterone and oestradiol doses (for example, 1.0 cm testosterone plus 0.1 cm oestradiol) that failed significantly to inhibit spermatogenesis when administered alone, markedly inhibited spermatogenesis when given simultaneously (Table 1). This interaction is apparently synergistic (supra-additive) because increasing the dose of either steroid by more than two-fold did not result in the major suppression of spermatogenesis obtained with the combination of testosterone and oestradiol.

The testes of each animal, treated with several of the testosterone-oestradiol combinations, were devoid of condensed spermatids and spermatozoa. At the lower dose of oestradiol-17β (0.1-cm implant), azoospermia was first obtained with a 2.5-cm Silastic implant of testosterone (Table 1). Consequently, further measurements were completed on animals receiving this steroid formulation.

The results in Table 2 suggest that the 2.5-cm testosterone-0.1 cm oestradiol treatment inhibited spermatogenesis indirectly by suppressing release of immunoreactive LH. We cannot, however, rule out a direct effect of oestradiol on testosterone secretion because Chowdhury *et al.*²⁶ suggested that oestrogen inhibits testicular steroidogenesis. Serum concentrations of testosterone and oestradiol were similar to control values in rats receiving the combination treatment (Table 2). Serum testosterone concentration reflected the free biologically active hormone, for the accessory sex organ weights of these rats were not significantly different from those of control rats.

These results raise two important questions about the mechanism by which testosterone-oestradiol combinations induced azoospermia, because the circulating levels of each steroid remained within the range typically noted in the sera of untreated adult male rats. First, why were concentrations of peripheral blood serum testosterone and oestradiol not increased? The probable answer is that testes of rats receiving the 2.5-cm testosterone-0.1-cm oestradiol treatment failed to produce testosterone. Testosterone secretion by *in vitro* perfused testes from control rats and rats with the 2.5-cm testosterone-0.1-cm oestradiol implants was 5.0 ± s.e.m. 0.4 (n=6) and 0.1 ± s.e.m. 0.03 (n=6) µg h⁻¹. Thus it seems reasonable to conclude that the implant was the major source of testosterone in the peripheral blood of the aspermatic rats. The steroids thus released replaced those usually

derived directly from the testis or indirectly from peripheral conversion of testicular steroids. Presumably testosterone from the implants was sufficient to maintain peripheral androgen-dependent functions but insufficient to maintain the high intratesticular concentration of testosterone^{25,27} required for spermatogenesis. The second question is: how did normal circulating titres of testosterone and oestradiol completely suppress circulating levels of immunoreactive LH? Probably because, in contrast to the episodic fluctuations in testosterone titres seen in normal males²⁸, implants release steroids at relatively constant rates^{17,29-30}. Thus it seems that sustained release of testosterone provides a more effective signal to androgen-dependent target tissues than the episodic fluctuations characteristic of intact animals^{25,31}.

Thus azoospermia can be induced in adult male rats with the appropriate testosterone-oestradiol formulation administered from a subdermal sustained release device. Preliminary results from our laboratory suggest that these azoospermic rats are sexually active but, predictably, infertile. Taken together, these results indicate that androgen-oestrogen combinations are an effective male contraceptive formulation in the rat, and thus the suggestion of Briggs and Briggs³² to test such combinations in the human male should be taken up.

We thank N. Ruiz Bravo, D. W. Carroll, N. Rugg and G. Zeller for technical assistance. Reagents used to assay serum LH and NIH-LH-S₁₉ were given by the NIAMD Hormone Distribution Program. This work was supported by a fellowship, a contract and grants from NICHD.

Anti-Müllerian hormone is a functional marker of foetal Sertoli cells

REGRESSION of Müllerian ducts in male foetuses is mediated by a testicular factor distinct from testosterone¹. This anti-Müllerian hormone (AMH), a protein which has been partially purified², is synthesised by foetal Sertoli cells³. In mammals the first stage of testicular differentiation involves the arrangement of sustentacular or Sertoli cells around the gonocytes and their encasement in testicular cords. Leydig cells appear later in the interstitium and their differentiation is correlated with the onset of steroidogenesis. We thought that there might also be a correlation between the initiation of testicular anti-Müllerian activity and the differentiation of Sertoli cells. Little work has been done on anti-Müllerian activity of the early foetal testis. During the initial stages of testicular organogenesis in the rat⁴ and the guinea pig⁵, AMH production is low, but the rapid pace of sex differentiation in most rodents hampers sequential study. Using sows (*Sus scrofa*), we have avoided this problem, and confirmed that the correlation exists.

Gestational age is known with great accuracy for sows of the large-white breed, bred at the INRA Zootechnical Centre. Foetuses were tested for testicular anti-Müllerian activity at between 27 and 34 d of gestation. Sex was determined by cytogenetic examination of hepatic cells⁶

Fig. 1 Chronological development of anti-Müllerian activity of the foetal pig testis. See text for details. Inc., incomplete.

Fig. 2 Histological aspect of the pig foetal testis studied by the silver impregnation method of Gomori¹³. a, 27 d: undifferentiated gonad; testicular cords are not clearly outlined. The mesonephros is on the right. b, 29 d: testicular organogenesis is complete; both the tunica albuginea and testicular cords are well differentiated.

from foetuses up to 30 d and by inspection of the genital tract in older ones. Testicular tissue was explanted on an agar-coated grid placed in a Petri dish filled with Ham's F12 medium, and the anti-Müllerian activity of between two and five explants was tested promptly by association with 14.5-d-old gonadless rat reproductive tracts⁷. In some 27 and 29-d-old pig foetuses one testis was cultured alone for 3 d before testing. The test was terminated after 3 d by fixation and the degree of regression of the Müllerian ducts of individual rat reproductive tracts exposed to testicular explants was scored as before⁸.

Figure 1 shows that anti-Müllerian activity increased steadily from negligible levels at 27 d to maximal values at 33 d. The ridit method^{9,10} of transformation of a non-parametric variable revealed a highly significant correlation ($r = 0.59$, $P < 0.01$) between anti-Müllerian activity and foetal age. We also found that anti-Müllerian activity could be acquired *in vitro*, though at a slower rate. Testes from 27-d-old pig foetuses after culture for 3 d had a significantly higher mean anti-Müllerian activity ($P < 10^{-1}$ by Student's paired *t* test) than the contralateral testes but lower activity ($P < 10^{-7}$ by Student's *t* test) than testes explanted at 30 d of gestation. The same tests performed on day 29 did not yield significant results (Table 1), probably because the basal level of anti-Müllerian activity was already high.

Gonadal sex is recognisable by electron microscopy as early as day 26 in the pig foetus¹¹. Using a light microscope, however, we were unable reliably to identify testicular organogenesis before day 29. Even then, primitive testicular cords, two to three cells wide, as described by

Table 1 *In vitro* development of anti-Müllerian activity of foetal pig testis

Age (d)	No. of pig foetuses	No. of tracts associated	Mean ridit \pm s.e.m.	Comparison with preceding group
27	25	25	0.246 \pm 0.030	
27 + 3*	25	25	0.440 \pm 0.048	$P < 10^{-3} \dagger$
30	10	35	0.697 \pm 0.017	$P < 10^{-7} (\ddagger)$
29	13	13	0.406 \pm 0.048	
29 + 3*	13	13	0.626 \pm 0.055	NS†
32	5	14	0.588 \pm 0.049	NS‡

The mean ridit^{8,10} expresses the probability that a rat reproductive tract selected from those exposed to pig testicular tissue from a given age group will have a greater degree of Müllerian regression than one selected at random from the reference population (here, all 246 tracts used in the study). NS, Not significant.

*Days in culture before test for anti-Müllerian activity.

†By Student's paired bilateral *t* test.

‡By Student's bilateral *t* test.

Moon and Hardy¹², were visible only after treatment with Gomori's silver impregnation¹³ (Fig. 2). At day 29, also, testicular anti-Müllerian activity becomes clearly demonstrable (Fig. 3). It seems therefore that cellular rearrangements characteristic of seminiferous tubule organisation must be completed before the activity of early Sertoli cells can be demonstrated physiologically. Similarly, Leydig cells differentiate in the interstitium at approximately day 31 (ref. 12), but peak testosterone concentrations are reached only by day 37 in the testis¹⁴ and day 55 in the plasma¹⁵.

Testicular anti-Müllerian activity wanes and eventually

Fig. 3 Anti-Müllerian activity of foetal pig testis, cocultured for 3 d with 14.5-d-old gonadless rat reproductive tract. *a*, 27 d at explantation: slight inhibition of the Müllerian duct is shown by the formation of a peri-Müllerian fibroblastic ring. *b*, 29 d at explantation: the Müllerian epithelium has almost completely disappeared, replaced by a fibrous whorl. M, Müllerian duct; W, Wolffian duct; T, pig foetal testis. Periodic acid Schiff stain was used.

vanishes after birth (see ref. 2 for review). This led Josso¹⁶ to conclude that AMH is a foetoprotein, that is no longer synthesised after the peri-natal period. In the light of the subsequent demonstration of the Sertoli-cell origin of AMH³, however, an alternative possibility should be considered: formation of the blood-testis barrier could prevent detection of AMH by inhibiting its release from testicular explants. After the formation of occluding junctions between adjacent Sertoli cells, the products of these cells such as inhibin or androgen-binding protein, accumulate in seminal fluid and epididymis^{17,18}, where a search for AMH might be rewarding for the understanding of the relationship between the function of the post-natal Sertoli cells and anti-Müllerian activity.

***In vitro* duplication and 'cure' of haemopoietic defects in genetically anaemic mice**

SEVERAL types of congenital, genetically determined macrocytic anaemias have been described in mice¹⁻⁴. These models offer a means of analysing the effects of mutations at defined loci on the ability of haemopoietic tissue to support stem cell proliferation and differentiation and allow studies on intrinsic defects in differentiation capacity of stem cells. But, analysis of these mutations and their implications in relation to pluripotential stem cell control have been hampered by lack of techniques, particularly of *in vitro* systems, for further defining regulatory interactions between stem cells and the haemopoietic inductive microenvironment. Here we report that the haemopoietic defects seen in W and Steel (Sl) mice have been successfully reproduced *in vitro*.

The pleiotropic effects of mutations at the W and Steel (Sl) loci include macrocytic anaemia, extreme radiosensitivity, sterility and defective pigmentation¹. The lesions in W mice are presumed to be due to intrinsic defects in haemopoietic stem cells, primordial germ cells and melanoblast precursors¹⁻⁴, whereas in Sl mice the defect resides within the environment into which these cells migrate, that is, the haemopoietic microenvironment, the gonads and skin^{1,2,4,5}. Support for this view is provided by the observation that pluripotential stem cells detected by the spleen

Table 1 Production of CFU-c and differentiating haemopoietic cells in continuous cultures of W/W^v , Sl/Sl^d and control bone marrow combinations

*Weeks from time of addition of the second marrow.

colony assay (colony-forming units, CFUs) are greatly reduced or absent in W anaemic mice but are present in normal numbers in Sl mice¹. Furthermore, W mice, both irradiated or unirradiated, support spleen colony formation after inoculation of bone marrow from non-anaemic litter mates or from Sl mice, whereas spleen colony formation does not occur in irradiated Sl mice after normal marrow inoculation^{1,2}. The haematological defects of W mice can, therefore, be cured by an inoculum of marrow cells from Sl mice and the macrocytic anaemia of Sl mice can be reversed after grafting of neonatal spleen or whole bone from W anaemic mice as a source of non-defective haemopoietic microenvironment. A culture system has been developed in which the proliferation of murine pluripotent stem cells (CFU-s), committed granulocyte-macrophage stem cells (CFU-c) and differentiating granulocytic cells can be maintained *in vitro* for several months^{3,4}. In this system mouse bone marrow-derived adherent cell cultures established for 3 weeks are re-inoculated with freshly isolated samples of syngeneic, allogeneic or semi-allogeneic bone marrow cells. The latter subsequently undergo proliferation for several months. This proliferation, differentiation and maturation of haemopoietic cells is dependent on the formation of a bone marrow-derived adherent population comprised of phagocytic mononuclear cells, 'endothelial' cells and giant fat-containing cells which apparently provide an *in vitro* microenvironment necessary for pluripotent stem cell renewal and differentiation⁷. Within this adherent layer extensive cellular interactions occur reminiscent of the intimacy of inductive cell interactions seen in embryogenesis. We have used this system to further explore the haemopoietic defects in W and Sl mice. To establish the cultures, the contents of a single femur from 10–14-week-old $WBB6F_1-W/W^v$ (W/W^v), $WCB6F_1-Sl/Sl^d$ (Sl/Sl^d) or their normal litter mates $W(+/+)$, $Sl(+/+)$, (Jackson Laboratories) were flushed into glass culture bottles containing 10 ml of Fisher's medium (Gibco), supplemented with antibiotics and 25% horse serum (Flow Labs), as described previously⁶⁻⁸. The cultures were incubated at 33 °C (a temperature shown to facilitate the development of the adherent layer of cells and subsequent growth of stem cells) in an atmosphere of 5% CO_2 in air. At weekly intervals the cultures were 'fed' by removal of half the growth medium and addition of an equal volume of fresh medium. Over a period of 2–3 weeks an adherent layer of cells became established and at 3 weeks all the growth medium and suspension cells were removed and the adherent layer re-fed with 10 ml of growth medium containing 10^7 freshly isolated bone marrow cells. The cultures were incubated at 33 °C and at weekly intervals were fed by removal of half the growth medium suspension cells and addition of fresh medium. The suspension cells removed at each weekly depopulation were assayed for granulocyte-macrophage progenitor cell (CFU-c) growth in soft agar using conditioned medium from a murine myelomonocytic leukaemic cell line (WEHI-3) as a source of colony stimulating factor.

Pooled cells from at least six cultures were used for each time point.

As shown in Table 1, extensive cell production was observed over a 6-week period in control cultures of non-anaemic $WBB6F_1$ ($W(+/+)$) or $WCB6F_1$ ($Sl(+/+)$) bone marrow. Production of CFU-c was likewise maintained at a high level throughout the period of culture. In contrast, cultures of Sl/Sl^d marrow or of W/W^v marrow showed considerably reduced production of both haemopoietic cells and CFU-c to as little as 1–3% of litter mate control cultures by 4 weeks. The morphology of the cultured cells showed a preponderance of differentiating granulocytic elements (40–75%) in the first 4–5 weeks of culture with an increasing proportion of phagocytic mononuclear cells at later stages. Transition to a macrophage morphology was observed earlier in W/W^v and Sl/Sl^d cultures than in the control cultures.

Allogeneic cultures were also initiated using Sl/Sl^d marrow to establish an adherent layer which was subsequently fed with W/W^v bone marrow. The additive effects of the Sl environmental defect and the W stem cell defect were apparent in this combination since cell production in culture was again markedly reduced relative to the control cultures and CFU-c were undetectable by the second week of culture. In addition, granulopoiesis in these cultures was no longer evident after the first week and thereafter cell proliferation was exclusively macrophage. The reverse combination using W/W^v to initiate the adherent population and subsequent feeding with Sl/Sl^d marrow resulted in a sustained high level of production of both differentiating haemopoietic cells and CFU-c throughout the period of observation.

While we have not as yet systematically monitored CFU-s in these cultures, the striking defect in generation of CFU-c and of differentiating haemopoietic cells seen in the W/W^v , Sl/Sl^d and $Sl/Sl^d-W/W^v$ cultures clearly points to an underlying defect at the level of interaction of the adherent marrow cells with the pluripotent stem cell.

But, no qualitative or quantitative defect was seen in the capacity of Sl/Sl^d marrow to generate an adherent layer and the defect may lie at the level of cellular interactions. Ultrastructural analysis of the *in vitro* microenvironment is being performed. The duplication of the W and Sl defect *in vitro* and our ability to 'cure' the defect by appropriate combinations of adherent cells and stem cells should permit further insight into genetically determined haemopoietic disorders and inductive cell interactions associated with pluripotent stem cell self renewal and differentiation.

HLA 'help' for human B2-microglobulin across species barriers

HLA antigens comprise products of what is commonly considered to be one of the most polymorphic systems presently known, occurring on chromosome 6. The HLA epitope is present only once¹ on a glycoprotein of molecular weight 45,000. In its naturally occurring form it is tightly, and probably obligatorily, but non-covalently bound to B2-microglobulin, (B2M), a protein of molecular weight 11,600 (ref. 2), determined by chromosome 15. B2M has substantial sequence homology with the C_H3 domain of IgG (ref. 3), and seems to be non-polymorphic. Precisely analogous associations occur between several other MHC antigens in rodents and fowl, and the equivalents of B2M in those species. This leads to the question as to why products of probably the most polymorphic systems should be so strongly associated with a non-polymorphic protein. In this paper we confirm that human B2M is immunogenic in phylogenetically distant species when the molecule is presented alone. When the species barrier is close, immunogenicity declines drastically as, for example, between man and other primate. In contradistinction, however, when B2M is presented bound to the HLA alloantigen-bearing chain, as occurs naturally, the complex is exquisitely immunogenic with respect to both B2M and the alloantigenic determinant if the species are closely related, and may decline as the species barrier widens. This is interpreted in terms of a modified 'intramolecular' help effect across a phylogenetically closely related barrier.

Free human B2M is clearly immunogenic in several

species at doses of 25–100 µg. As might be expected, antibody titres in chickens are higher than in mammals, reflecting a wider species barrier. Hyperimmune rabbit antisera to the unseparated proteins in human serum have also been examined (last line, Table 1). Although B2M was detected in the immunising inoculum at levels of 1–2 µg ml⁻¹, no anti-B2M antibodies were found in the resultant antisera, confirming that, at this dose, B2M is essentially non-immunogenic.

Much smaller doses (0.1–0.2 µg) of B2M bound to HLA antigen are highly immunogenic in rabbits and anti-B2M antibodies rise to levels essentially similar to those found with much higher doses of B2M used alone. As expected, the sera are cytotoxic for peripheral human lymphocytes. Furthermore, the immunogen used did not inhibit the lysis of B cells by a rabbit anti-human B cell-specific antiserum⁴, thereby suggesting the absence of human Ia antigens in the preparations. (Contamination with Ia antigens is, in any case probably ruled out by the anion exchange and gel filtration purification procedures used.)

Absorption of the rabbit anti-HLA sera with human erythrocytes (which are lacking in B2M and HLA antigens), did not reduce the lytic titre by much. Absorption with platelets or crude human spleen membranes negative for the immunising HLA specificity were, however, much more effective in removing lympholytic antibodies. Nevertheless, drastic absorption (>95%) was necessary before moderate HLA specificity (SR>5) was revealed. Antibodies to B2M contributed substantially to the original cytotoxicity. This is most clearly shown by passing antiserum through a B2M affinity column, when 90–95% of cytotoxicity was removed; neither was there a notable increase in HLA allospecificity following such treatment.

In spite of this low level of allospecific globulin, such lytic rabbit sera are substantially inhibited by HLA antigens, thereby confirming earlier work⁵ in which nonspecific cytotoxic xenoantisera prepared against H2 or HLA antigens in soluble or cellular form were inhibited only by those areas of a gel filtration chromatogram (of crude soluble membrane proteins) containing mouse H-2D and H-2K alloantigens or human HLA-A, B, and C alloantigens respectively. Rabbits are known to raise antibodies to at least one common

Table 1 Sensitisation of non-primate species to human B2M

Species*	Injected protein per dose (µg)	B2M form	Adjuvant†	Anti-B2M‡ titre	Human lymphocytotoxic 50% Cytotoxic titre§	SR¶
Chicken	50	Free	C,A	5,000	500 (chicken complement)	1.0
Rat	25	Free	C,A	648 ± 233	—	—
Guinea pig	50	Free	C,A	358 ± 275	—	—
Rabbit	50–100	Free	C,A	1,107 ± 407	60 ± 16	1.0
Rabbit	0.5–1.0**	Papain solubilised HLA antigen††	I,A	838 ± 435	889 ± 265	1.2 ± 0.2
Rabbit	Human serum proteins	Free	C,A	0	—	—

*Groups of four or five animals were usually used. When free B2M was used as antigen, progressively lower doses gave correspondingly lower anti-B2M responses. No detectable response was produced in guinea pigs, chickens, or rabbits with repeated injections of less than 5.0 µg B2M in adjuvant.

†C, Complete Freund's adjuvant; A = alum precipitate; I = incomplete Freund's adjuvant.

‡5 µl of ¹²⁵I-B2M solution was added to 8 µl volumes of fivefold dilutions of antiserum in diluent. After incubating at room temperature for 1 h, 0.180 ml 19% Na₂SO₄ solution was added followed by further incubation at room temperature for 1 h. After centrifugation at 1,000g for 5 min, 50% of the supernatant was sampled. Results were plotted as the percentage radionuclide remaining in solution against antiserum dilution in the reaction volume. The titre of an antiserum is the dilution at which 50% of the nuclide is precipitated. Control samples contained diluent in place of antiserum and results were corrected according to the titration value given by a reference chicken anti-human B2M serum.

§Estimated in microtitre plates using 25-µl volumes of lymphocytes, antiserum dilutions, and rabbit complement, and a Trypan blue indication of cell death.

¶SR, Specificity ratio; the ratio of titre with cells positive or negative for an HLA specificity, based on analysis of a population of 20 cell types covering the relevant specificities.

||Values obtained after at least four booster injections in the case of free B2M, but after only two boosts of HLA antigens.

**The protein content of HLA antigen is based on an assumed final purity of 10%, validated by radioimmunoassay of B2M content.

††Specifically purified and separated HLA-A1, A2, B8, and B12 papain-solubilised antigens were used in a total of six rabbits.

Fig. 1 Associative recognition in alloantigens. 'Help' or associative recognition within a species (man 1-man 2) for antibody production to B2M-associated alloantigens occurs in a primary response only when other MHC region products are present at the same time. It seems likely that these products are required to be on the same cell. If spatial relationships are vital in the presentation to recognition units on T cells, then surface mobility, that is, a living membrane will be an equally vital feature of the allogeneic stimulus. These demands disappear when epitopic differences are revealed in the B2M component of alloantigens as in xenogenic but phylogenetically close sensitisations (man-primate). Inherent in this argument is the assumption that the remainder of the alloantigenic glycoprotein is poorly immunogenic for whatever reason, and will remain essentially as weak between related species as it does within species. When the barrier is wide, however (man-rabbit), even this restriction disappears, and enough differences occur between the respective species alloantigens that multiple dual recognitions can arise at various places on the sensitising molecule.

species determinant on the alloantigen-bearing chain of all HLA antigens⁶.

Thus antisera prepared in rabbits, even to purified HLA antigens, are not likely to produce reagents of great value in revealing HLA allospecificity on human lymphocyte targets using lytic assays. The rabbit might be expected to differ from man at several places other than the HLA epitope on the HLA chain, as well as at several places on B2M, so allospecific globulins would comprise only a minor portion of the total antibody formed against the whole alloantigen chain with its attendant B2M. The cytotoxins directed against non-allospecific determinants, both on the HLA chain and on human B2M, can be removed by appropriate absorption with specific immunogen-negative tissue. Such an absorbed antiserum, albeit of low cytotoxic titre, has already been extensively examined (χ^2 with respect to HLA-A1=26.9, cited in ref. 7). What is interesting is that substantially augmented immunogenicity to human B2M is observed when this protein is associated with HLA alloantigen and presented across a species barrier.

The results obtained by immunisation of *Macaca irus* monkeys were quite different. After extensive immunisation with free B2M at doses similar to those which readily produced antibodies in several other non-primate species, much lower humoral immunity was observed with this primate species. Not only were antibody titres lower, but a response was only obtained after six courses of immunisation, compared with two in non-primate species, and the titre has not increased on further immunisation.

Purified HLA substances have previously been shown to be highly immunogenic across this close barrier, producing very high titres of lymphocytotoxic antibodies with a few micrograms of material^{8,9}. The absorbed sera (SR 13.8 \pm 5.6) showed excellent accord with well defined single HLA specificities in population studies. Both the specificity of the unabsorbed sera (SR 4.8 \pm 1.1), and the yield following absorption indicated that anti-HLA globulins formed the majority of the total lympholytic antibody, in contrast to the results obtained with rabbits and shown earlier.

The results of Table 2 indicate that the limited non-

specificity of the primate antisera is largely attributable to their anti B2M content. First, very high titres of anti B2M antibodies were found in the radioimmunoassay. These levels are often substantially higher than those found in non-primate antisera produced by immunisation with much larger quantities of free B2M. (It should be stressed that the amount of B2M administered to primates in HLA-complexed form is 500–1,000-fold less antigen than the dose of free B2M used.) Second, when an animal previously sensitised with HLA-A2 antigen was boosted after 3 yr with free B2M, high levels of anti-B2M were immediately produced, indicative of a pre-existing immunity. Third, all nonspecific cytotoxic activity can easily be removed by a B2M affinity column. In a typical experiment, the anti-HLA activity was recovered in good yield (>90%) following such treatment and was of excellent specificity (SR > 100). These results illustrate that most of the total cytotoxic activity is attributable to specific anti-HLA antibodies, and the remainder is due to nonspecific anti-B2M antibodies. Furthermore, immunosorbents prepared from B2M-absorbed primate monospecific antisera of high titre represent powerful yet simple tools for the purification of HLA antigens from crude starting material, without recourse to prolonged chromatographic separations.

Apart from the mutual augmentation effect of HLA on B2M across a close species barrier, a further interesting feature of all the primate antisera is that they uniformly fail to precipitate B2M either directly or in gel diffusion plates. This is in contrast to the rat, guinea pig, chicken and rabbit antisera, which all precipitate B2M from solution. Preliminary results based on gel filtration of antigen-antibody complexes between primate antisera and B2M indicate that the anti-B2M antibodies are directed against only two sites on the B2M molecule, regardless of whether they are produced in response to free or HLA-linked B2M. This would preclude any lattice formation necessary to produce precipitation with antigen, whereas the radioimmunoassay used here¹⁰ for quantitation of anti-B2M antibodies is not dependent on direct precipitating properties of the antiserum. Rabbit antisera seem to contain antibodies

Table 2 Sensitisation of *Macaca irus* primates to human B2M

**Responses were detectable after two boosts, titres shown are after three boosts.

directed against three or four sites, and chicken sera detect at least six sites on B2M which would accord with their precipitating properties. The similarity between primate antisera raised either to free B2M or to the HLA-linked B2M in terms of precipitating properties and the number of epitopes recognised, renders it unlikely that conformational changes in B2M are imposed as a consequence of the HLA association and that this results in the augmented immunogenicity noted here.

It may be concluded from these experiments that although free B2M is quite immunogenic across wide species barriers, the immunogenicity declines when the barrier is phylogenetically close. The situation is quite different when B2M bound to HLA antigens is considered. B2M is able to derive immunogenic 'help' by associative recognition, because of its peculiar association with these MHC antigens. Although B2M is not covalently linked to HLA, the bonding is nevertheless strong, in that low pH or very strongly ionic detergents are required to separate the protein chains. The help provided by the alloantigen across a species barrier may thus be intermediate between the two types defined^{11,12}. 'Intramolecular help' refers to a situation where helper and principal determinant are on the same molecule. 'Inter-molecular, intrastructural' which may be somewhat less effective (N. A. Mitchison, personal communication), refers to helper and principal determinants being on different molecules. Because B2M and its attendant alloantigen mobilise jointly on cell surfaces ('capping'), however, and remain tightly bound when solubilised from membrane by enzyme, non-ionic, or weakly ionic detergents, they may for most purposes be considered as being on the same molecule and therefore presented as an immunogenic unit in circumstances such as tissue grafting or the experiments described here with HLA antigen.

Recent evidence (in rats¹³) suggests that within a species, both Ia and AgB antigens must be presented on the same living cell in order to provoke anti-AgB antibodies. Soluble alloantigens, or cellular membranes which do not express Ia antigens, are essentially non-immunogenic in a primary response. Primed animals may be different, however, and it is worth noting that once sensitisation has occurred, help can be provided for particular H2 components by other MHC gene products and/or minor non-MHC antigens¹⁴.

Immunisations across species barriers with purified HLA antigens present quite a distinct contrast. Provided there is some difference at B2M between the species, then even when donor and recipient are phylogenetically close and their MHC antigens might therefore be expected to be quite similar, the high degree of MHC polymorphism is almost certain to ensure a second (HLA) epitopic difference on the two-chain antigen molecule, thereby providing an opportunity for associative recognition and help. It should also be borne in mind that a large proportion of T lymphocytes

is able to recognise MHC antigens within a species^{15,16}, and therefore probably to recognise analogous MHC antigens across a close phylogenetic barrier. It would be expected then that the help provided would be very substantial because of this large existing clone from which T helpers could be derived. This is proposed as the explanation for the high titres of anti-B2M antibodies found here in primates, and it occurs essentially because of the B2M–HLA association. Furthermore, the high degree of allospecificity, especially when anti-B2M antibodies are removed, suggests that the non-alloantigenic portion of the glycoprotein chain is only poorly immunogenic between related species. This conclusion was reached earlier in other primate experiments¹⁷. In dosage terms, the very small amount of soluble alloantigen is as effective outside the species as the same quantity of alloantigen presented in cellular form on viable lymphoid tissue within the species of origin. These inter-relationships are summarised diagrammatically in Fig. 1, where allogeneic, and close or distant xenogeneic immunogenicity is depicted.

In the xenogeneic (mouse–man) primed lymphocyte typing assay it has been found¹⁸ that both the stimulating and target antigens are probably identical to those involved in the allogeneic mouse mixed lymphocyte reaction. The role of B2M was not examined, but when taken in conjunction with the findings reported here, it suggests that the part played by this molecule in xenograft rejection and therefore in species discrimination and interfertility will warrant further investigation.

It is also possible to imply that HLA antigens or their equivalent in other species may serve as 'super carriers' for artificially attached haptens and epitopes when the MHC barrier is crossed within a species or in a closely related species, and this implication is presently under investigation. The examination of what may thus be considered as modified 'non-self' has obvious relevance to the present interest in altered 'self' as a possible mechanism whereby animals combat viruses¹⁹.

In a radiation chimaera, host H-2 antigens determine immune responsiveness of donor cytotoxic cells

CELL membrane structures controlled by genes in the major histocompatibility complex (H-2 in mice) are involved in most immune interactions between T lymphocytes and other cells¹. Cytotoxic T lymphocytes (CTL) immunised against viruses², haptens³, minor histocompatibility antigens⁴ or tumour antigens⁵, are specific for self H-2 antigens as well as for the foreign antigen. But CTL are not restricted to recognising antigens in combination with only self H-2. H-2^d homozygous CTL which have matured in an irradiated H-2^d/H-2^k host can respond to antigen plus H-2^k in addition to antigen plus H-2^d (refs 6-8). It is not known whether the H-2 environment in which T cells mature influences their range of specificity, that is, whether CTL from a normal mouse can respond quantitatively as well to antigen plus foreign H-2 as they do to antigen plus self H-2. These experiments were designed to test this influence. The results suggest that host H-2 antigens do exert an effect on the specificity of T-cell responses.

A single suspension of bone marrow cells from F₁(BALB/c × BALB B) (F₁(C × C B), H-2^d/H-2^b) mice was used to reconstitute groups of lethally irradiated parental mice, C(H-2^d) ([F₁ → C] chimaeras) and C.B(H-2^b) ([F₁ → C.B] chimaeras). Eight weeks later these chimaeric mice and normal F₁(C × C.B) mice were primed against minor H antigens by injecting 8 × 10⁶ F₁(B10 × B10 D2) (H-2^b/H-2^d) spleen cells. The B10 background offers more than 30 minor histocompatibility antigenic differences that can be recognised by BALB mice^{9,10}. Some weeks later the primed spleen cells were boosted in culture with irradiated F₁(B10 × B10 D2) stimulator cells and assayed for cytotoxicity 5 d later.

Following this immunisation procedure, cells from normal F₁(C × C.B) mice lysed B10 targets and B10 D2 targets almost equally (Table 1). (The two activities are mediated by separate

pools of CTL²⁻⁴) The chimaeras responded differently. In the same conditions of immunisation with F₁(B10 × B10 D2) cells, they responded preferentially to the minor antigens in association with the H-2 antigens of the host CTL from the [F₁ → C] chimaeras killed B10.D2 targets better than B10 targets, whereas CTL from [F₁ → C.B] chimaeras lysed B10 targets better than B10.D2 targets (Table 1).

Spleen cells from five chimaeras were assayed for their content of host and donor cells at time of killing. Complement-mediated lysis with H-2^b anti-H-2^d serum and with H-2^d anti-H-2^b serum indicated that in all cases at least 85% of the cells were of F₁ (donor) origin. The cytotoxic effector cells were also lysed with anti-H-2 serum and complement just before the ⁵¹Cr-release assay (Table 2). Here, the [F₁ → C] chimaera cells lysed B10.D2 targets ninefold more efficiently than they lysed B10 targets (data not shown). The killer cells were treated with antiserum plus complement, washed, and assayed for lysis of labelled B10.D2. Table 2 shows, most importantly, that BALB/c anti-C57BL/6 (anti-H-2^b) serum reduced the cytotoxic activity 86% compared with controls. This antiserum does not lyse BALB/c effector cells. Therefore, at least 86% of the CTL were of F₁ bone marrow origin.

These experiments show that H-2^d/H-2^b cytotoxic cells which mature in an irradiated H-2^d host respond preferentially to antigens plus H-2^d, whereas H-2^d/H-2^b cells which mature in an irradiated H-2^b host respond preferentially to the same antigens in conjunction with H-2^b gene products. The experiments were designed to test the 1971 Jerne hypothesis¹⁴, or a modified version of it^{4,15}. The hypothesis accepts that a somatic theory of generation of receptor diversity is correct and proposes that self-H-2 antigens drive the diversity. Immature T cells first express an anti-self-H-2 receptor, leading to proliferation and to accumulation of V gene mutations until there is no significant reaction with self-H-2. According to this hypothesis, the receptor repertoire of A strain T cells which had matured in an A environment would be quite different from that of A strain T cells which had matured in a B environment. The results presented here are compatible with this hypothesis and with another theory of 'adaptive differentiation'¹.

There is an alternative explanation of the results. It may be that the host haplotype preference seen at the level of effector CTL does not reflect a bias in specificity at the level of precursor CTL. The H-2^d/H-2^b precursor CTL in the H-2^d host may have exactly the same range of reactivity as those in the H-2^b host. The haplotype preference of the effector CTL would then be due to the way antigen is presented to CTL precursors. Even though the immunogen (B10 minor antigens) was introduced on H-2 heterozygous cells, the antigen which was responsible for priming CTL may have been processed antigen presented on radiation resistant host cells⁴. In the [F₁ → C] chimaera such radiation-resistant antigen-present-

Table 1 Specificity of H-2^d/H-2^b cytotoxic cells from normal and chimaeric mice

Chimaera [F ₁ → C]	F ₁ (B10 × B10 D2)(H-2 ^b /H-2 ^d)	19.3	72.7	2.9	ND	0.02
Chimaera [F ₁ → C B]	F ₁ (B10 × B10 D2)(H-2 ^b /H-2 ^d)	51.8	29.1	0.1	ND	5.2
Normal F ₁ (C × C B)	C3H(H-2 ^k)	4.5	3.8	71.5	ND	—
Experiment 2						
Normal F ₁ (C × C B)	F ₁ (B10 × B10 D2)	54.8	68.4	ND	0.9	0.5
Chimaera [F ₁ → C]	F ₁ (B10 × B10 D2)	4.8	80.5	ND	1.5	<0.02
Chimaera [F ₁ → C B]	F ₁ (B10 × B10 D2)	61.3	8.8	ND	0.1	>43.0

*Chimaeras were prepared as follows: BALB/c(C(H-2^d)) and BALB.B(C B(H-2^b)) mice were irradiated with 850 R and reconstituted on the same day with 13.4 × 10⁶ anti-Thy-1 plus complement (C)-treated F₁(C × C B) bone marrow cells. Eight weeks later they were immunised.

†Primed against minor H antigens by injecting 8 × 10⁶ viable F₁(B10 × B10 D2) spleen cells intraperitoneally. Spleen cell suspensions were prepared 4 weeks later (experiment 1) or 6 weeks later (experiment 2), and boosted for 5 d in culture with an equal number of 1,000 R irradiated F₁(B10 × B10 D2) or C3H/He/J spleen cells as described previously¹¹.

‡2-d con A (conavalin A) blasts were labelled with ⁵¹Cr-sodium chromate and used as targets as described previously¹¹. Serial dilutions of the killers were assayed against a constant number of targets, and the figures for specific lysis presented here are for a killer:target ratio of 100:1. Spontaneous release of ⁵¹Cr varied from 18.1-22% in experiment 1 and from 9.6-13.7% in experiment 2.

§Calculated from the titrations of killers:targets^{12,13}. For example, in experiment 1, the [F₁ → C] cells lysed B10 D2 targets 50 times better than they lysed B10 since a 100:1 ratio caused 19.3% specific release from ⁵¹Cr-B10, whereas the same amount of specific lysis of ⁵¹Cr-B10 D2 was obtained at a ratio of 2:1. ND, Not determined.

Table 2 Sensitivity of chimaera cytotoxic cells to anti-H-2 serum plus C'

Cytotoxic cells*	Treatment of effector cells†	% Specific lysis of ⁵¹ Cr-B10 D2‡	% Reduction in lytic activity§
[F ₁ →C] anti-F ₁ (B10×B10 D2)	Medium	34.0	—
	Normal B10 serum + C'	34.3	0
	Anti-H-2 ^b + C'	9.8	86
	Anti-H-2 ^d + C'	5.1	94

*[F₁→C] chimaeras were primed *in vivo* 8 weeks after reconstitution, their spleen cells boosted in culture 20 weeks later and assayed for cytotoxicity on day 5 of culture.

†BALB/c anti-C57BL/6 and C57BL/6 anti-BALB/c sera were prepared by hyperimmunisation with spleen cells. Effector cells were incubated with mouse sera 1:2, washed, and incubated in guinea pig serum 1:9 as a source of complement (C'). Cells were re-suspended to the same volume and assayed.

‡Con A blasts from B10 D2 mice were labelled with ⁵¹Cr and used as target. Data presented are for original number of responder spleen cells: target cells of 7:1. Spontaneous release of ⁵¹Cr was 20.6%.

§Calculated from the titrations of killer: targets as in Table 1.

ing cells would be homozygous H-2^d and would naturally stimulate only anti-B10 D2(H-2^d) CTL, not anti-B10(H-2^b) CTL. Experiments to decide between these interpretations are in progress.

Cytotoxic T lymphocytes induced in mice by inactivated influenza virus vaccine

THERE is abundant evidence that T cell-mediated lysis of virus-infected target cells generally requires H-2K or H-2D region histocompatibility between cytotoxic T lymphocytes (CTL) and target cells^{1–4}. The biological basis of this requirement is still uncertain. Studies using chimaeric mice suggest that T lymphocytes are selectively sensitised by the viral and H-2 antigens expressed on the infected cell and that killing only occurs when the target cell shares H-2K or H-2D identity with the immunising virus-infected cell⁵. It is important to determine whether virus infection of the host tissue is, in fact, necessary for specific CTL immunity to develop. If this were so, the use of inactivated virus or purified viral antigens would not be suitable as vaccines against diseases in which CTL were required to afford optimal protection. We report here that inactivated influenza virus vaccines are, in fact, quite capable of evoking haemagglutinin specific CTL.

Epidemiological and experimental evidence indicate that protective immunity against influenza virus is principally directed against the virus haemagglutinin^{6,7}. We have recently described the development of haemagglutinin-specific CTL in influenza-infected mice⁸. This finding is consistent with these cells playing an important *in vivo* function in influenza immunity. Our finding contrasts with

Fig. 1 Specific immune lysis by spleen cells of BALB/c mice immunised intraperitoneally with 5,000 chick cell haemagglutinating units (HAU), (○), 500 HAU (Δ) and 50 HAU (□) of A/Port Chalmers formalin-inactivated whole virus influenza vaccine. The spleen cells were tested at a 100:1 ratio on A/Port Chalmers-infected syngeneic kidney-derived cells in an 18-h ⁵¹Cr-release cytotoxicity assay as described previously¹⁰. The cytotoxic cells generated in vaccine-immunised mice were shown to be T cells by the removal of cytotoxic activity using anti-θ antiserum plus complement. Thus, whereas untreated spleen cells and spleen cells treated with complement alone achieved 42.3 and 37.0% specific lysis respectively, spleen cells treated with anti-θ antiserum plus complement achieved 7.9% specific lysis, which was not significant (*P* > 0.5).

recent studies which failed to demonstrate haemagglutinin-specific CTL in influenza-infected mice^{11–13}. These studies differed from our study, however, in the use as target cells of relatively non-permissive influenza-infected transformed cell lines rather than productively-infected normal tissue-derived target cells¹⁴. In the present study we have similarly tested mice inoculated with influenza vaccine, for haemagglutinin-specific CTL reactive with productively-infected target cells. The virus vaccines used contained an early H3N2 virus strain⁹, A/Aichi/68; a later virus of the same H3N2 subtype, but with a serologically distinguishable haemagglutinin, A/Port Chalmers/73; and an unrelated influenza B virus, B/Hong Kong/72. The target cells were syngeneic kidney-derived infected cells¹⁰. The experiment was carried out in both BALB/c mice (H-2^d) and C3H mice (H-2^k).

Figure 1 depicts the CTL response we observed in BALB/c mice inoculated intraperitoneally with various doses of A/Port Chalmers vaccine (virus vaccine supplied by Merrell-National Laboratories). Significant cytotoxic T-cell response was observed with each of the doses tested. To determine whether the response was restricted to target cells histocompatible with the immunised mice, we tested spleen cells from BALB/c and C3H immunised mice on syngeneic and allogeneic virus-infected target cells. As indicated in Table 1, the cytotoxic response was detectable only on the syngeneic virus-infected target cells. Specificity of the CTL for the haemagglutinin antigen of the immunising vaccine virus was shown in the experiments recorded in Table 2. Thus, CTL-distinguished target cells infected with the immunising strain H3N2 influenza virus, from target cells infected with a serologically different but related

Table 1 Virus specificity of cell-mediated lysis by CTL in influenza vaccine immunised mice

Vaccine virus used as immunogen	Specific immune lysis of target cells*		
	A/Port Chalmers-infected	A/Aichi-infected	B/Hong Kong-infected
A/Port Chalmers/73	96.6	6.2	8.8
A/Aichi/68	5.2	67.0	2.7
B/Hong Kong/72	—6.9	3.2	63.4

*Spleenic lymphocytes were tested 8 d after intraperitoneal immunisation.

BALB/c	1.7	21.3
C3H	33.4	1.9

*Splenic lymphocytes were tested 5 d after intraperitoneal immunisation.

H3N2 strain Increasing knowledge is becoming available concerning the structure of the influenza virus haemagglutinin antigen. It should be possible, therefore, to extend the studies reported in this paper to define the precise cellular-antigen interactions involved in the generation of CTL and to determine the basis of the H-2 compatibility requirement between CTL and virus-infected target cells.

The finding that inactivated influenza virus vaccine can induce a haemagglutinin-specific CTL response is in agreement with the recent finding of Schrader and Edelman¹⁵ that inactivated Sendai virus can elicit CTL in primary cultures of mouse spleen cells¹¹, and the observation of Wiktor *et al* that CTL develop in mice inoculated with inactivated rabies virus¹⁶. Together, these findings provide considerable support to the potential development of purified protein vaccines for use against chronic viral diseases and malignancy where T cell-mediated, rather than humoral, immunity seems to be deficient.

We thank Mr S. Daniel for assistance.

Induction of plaque-forming cells in cultured human lymphocytes by combined action of antigen and EB virus

PRIMARY *in vitro* immune responses of human peripheral blood lymphocytes (PBL), desirable for both basic and clinical studies, have been rather difficult to achieve. Positive results were obtained when other stimulatory factors, besides antigen, were given to the cells^{1,2}, and other reports have suggested a critical role of antigen presentation and antigen concentration^{3,4}. In view of the difficulty encountered in stimulating an antibody response with antigen alone,

we have attempted to use Epstein-Barr virus (EBV) together with sheep red blood cells (SRBC) to induce a specific response. Human B lymphocytes possess membrane receptors for EBV^{5,6} and the virus stimulates DNA synthesis in human PBL⁷, so EBV provides a 'nonspecific' stimulus in addition to the specific one given by the antigen. We report here that use of EBV and SRBC in this way consistently induces an anti-SRBC response from human PBL.

Human PBL, from different donors, were cultured in the conditions previously described¹. The source of the virus was the EBV-secreting marmoset lymphoid cell line B 95-8 (ref. 8). Table 1 shows that the appearance of plaque-forming cells (PFC) was a rare and inconsistent event when human PBL were cultured in the presence of SRBC only. Addition of EBV alone led, with some donors, to a measurable but transient appearance of background PFC. But, when both antigen and virus were present in the culture from the very beginning a significant immune response was regularly observed with the majority of donors. Ultraviolet inactivation of the virus did not abrogate this effect. There was no stimulation if the addition of the virus was delayed by 48 h, or if culture supernatant freed of virus was added.

To determine whether the PFC responses were antigen specific, either SRBC or horse red blood cells (HRBC) were added to cultures in the presence of EBV. Each culture was screened separately for PFC using SRBC and HRBC as indicator cells. The results in Table 2 show that the responses obtained were specific for the antigen added. The occasional appearance of nonspecific PFC with some donors could be due either to an antigen-independent response induced by EBV or to a cross-reactivity between the two antigens.

Though the basic phenomenon described above is remarkably reproducible, the kinetics and height of the response vary considerably. PFC levels were very low before day 4 and usually reached a maximum between days 7 and 9. While in some cases PFC were present over 2 or 3 days only, cells of other donors yielded PFC in high numbers over 1 week or more. In some experiments a second burst of PFC (occasionally amounting up to a small percentage of

Human lymphocytes were prepared from heparinised blood by centrifugation on a Ficoll-Urovison gradient. Adherent cells were removed and the non-adherent cells were suspended at a density of 9×10^6 per ml in tissue culture medium according to previously described methods² with a few modifications. Foetal calf serum was substituted with human AB serum, heat inactivated and absorbed three times in the cold with SRBC. The concentration of AB serum was 8% in the medium and 10% in the nutritional mixture. Antigen was added (0.05 ml of 1% SRBC per ml of culture) and the cell suspension was distributed in aliquots of 0.1 ml in the wells of Microtest plates. 50 μ l of 10-fold concentrated virus-stock⁸ were added to each well. The cultures were incubated at 37 °C in the presence of 5% CO₂, and 24 h after initiation 50 μ l of nutritional mixture were pooled in each well. At the time of assay the content of five wells was pooled, washed and plaqued with a modification of the haemolysis in gel method². Figures represent PFC per well.

	HRBC	5	12	0	55	0	2,400

Procedure as in the legend to Table 1. The cultures stimulated with HRBC received 0.05 ml of 1% HRBC per ml of culture. The AB serum used for these cultures was absorbed three times in the cold with HRBC. Figures represent PFC per well.

the recovered viable cells) arose beyond day 10, suggesting a biphasic event (data not shown). Moreover, comparing different culture wells of the same preparation, large variability was observed in some experiments but not in others. There were also significant differences between donors: among the 35 tested, some gave consistently high responses in up to six experiments over a period of 8 months, while others responded poorly and a few not at all. Whether this is due to technical reasons or reflects differences in the immune status of the donor is under investigation. There is apparently no correlation between the capacity to respond in the present system and previous exposure to EBV, as judged by the presence of anti-viral antibodies in the serum.

The mechanism of action of EBV is a matter for speculation, but any model would have to consider either direct action of the virus on B cells or induction of helper T cells.

In the presence of antigen the binding of EBV to its receptor could provide a sufficient signal for B-cell triggering, and bypass the requirement for T-cell help. In its extreme form this concept would attribute to the EBV receptor a role in the binding of physiological T-cell factor(s)⁸. But, what we observed could just as well be an instance of a much more general phenomenon: the threshold for B-cell induction is lowered by the binding of some agent to its appropriate receptor on the cell surface. It has been shown¹⁰ that binding of an antibody directed against a surface component on mature murine B lymphocytes markedly enhances the appearance of PFC in conditions of suboptimal antigen doses and can substitute for T-helper activity. Furthermore, EBV can act as a polyclonal activator¹¹. Its mode of action may therefore be analogous to the stimulatory effect of lipopolysaccharide (LPS) on the immune response to various antigens in mice¹².

The alternative model implies that EBV indirectly activates T cells which would then provide, in the presence of antigen, sufficient help for B-cell induction. Support for this interpretation comes from the clinical syndrome of infectious mononucleosis. During the acute phase of this EBV-induced disease mostly thymus-derived lymphocytes proliferate and appear in the peripheral blood and in the T-dependent areas of lymph nodes¹³. It seems that the stimulus for the T-cell response comes from virus-determined structures on B cells⁹. A similar mechanism in our *in vitro* system could provide sufficient T-cell help to promote the specific antigen-dependent response. Experiments are in progress to determine the mode of action of EBV by culturing separately purified populations of T and B lymphocytes.

We thank Ms Lotte Kuhn for technical assistance, Drs J. Zeuthen and G. Klein for providing the B95-8 cell line,

and Drs H. Cosenza, S. Fazekas de St Groth and S. de Petris for useful discussions.

EB virus-induced B lymphocyte cell lines producing specific antibody

EPSTEIN-BARR virus (EBV) is a lymphotropic herpesvirus that converts normal human B lymphocytes into established lines. This 'immortalisation' preserves the characteristics of the original B cell, including EBV receptors, complement receptors, surface immunoglobulin and secretory immunoglobulin. Surface immunoglobulin is most frequently IgM. EBV-immortalised lines carry multiple copies of the viral genome, detected by nucleic acid hybridisation, and regularly express an EBV-specific nuclear antigen, EBNA. It has been suggested¹ that all B-cells carry EBV receptors. If so, and if all B cells can be transformed into lines by EBV, it should be feasible to establish permanent lines from B lymphocytes capable of producing specific antibodies against appropriate antigens. Clearly, in view of the polyclonal transformation obtained after infection of B lymphocytes with a transforming virus strain, for example, B95-8, it will be necessary to pre-select lymphocytes with the appropriate antigen combining site. Rosetting with antigen-coupled erythrocytes is one of the conceivable methods for such pre-selection. While this will select lymphocytes with the appropriate surface immunoglobulin receptors, it was recently shown that EBV-transformation activates normal lymphocytes and induces the release of secretory immunoglobulin². If the procedure is successful, the established lines might therefore be expected to carry the appropriate surface receptor and also to secrete the corresponding antibody. This was actually found in this study, opening the way to the establishment of cell lines producing specific antibodies of choice.

We have selected as lymphocyte donors three members of the laboratory staff in Helsinki who were shown to have relatively high natural antibody titres against the synthetic hapten NNP (4-hydroxy-3,5-dinitrophenacetic acid) and whose peripheral blood lymphocytes showed specific NNP rosetting.

Lymphocytes were isolated on Ficoll³ and rosetted with autologous-NNP coupled erythrocytes⁴. NNP-azide, prepared according to Brownstone *et al.*⁵ was coupled to erythrocytes using a hapten concentration of 2 mg ml⁻¹ in the final conjugation mixture with the erythrocytes⁶. The percentage of rosettes ranged between 0.08 and 0.6% of the total lymphocytes. The rosettes were spun down on Ficoll-Isopaque (density 1.077) for 20 min at 400g to remove the non-rosetting cells, and then infected with B95-8-derived EBV. As the virus source, we used supernatants of

Table 1 Anti-NNP rosette and plaque formation by EBV-transformed lines derived from NNP rosetting and unfractionated cells, respectively

E (Unf)	Unfractionated	0	0	100	+
EP re-selected	NNP re-selected	86	69	100	+

*Rosette-forming cells (RFC): 5×10^6 cells in 1 ml were washed and mixed with 0.01 ml human NNP-coupled erythrocytes, spun down for 15 min by low velocity centrifugation at 4°C, and incubated further for 30 min at 4°C. The % of rosettes was assessed after resuspension of the pelleted cells. No rosettes were formed with uncoupled erythrocytes.

†Plaque-forming cells (PFC): equal volumes of 1/5 guinea pig serum, 10% NNP-coupled erythrocytes and different numbers of cells were mixed and inserted between two slides⁸. Plaques were counted 90 min later. The plaques were inhibited if 10^{-4} M NaN₃ was added to the mixture. No plaques were detected with uncoupled erythrocytes. ND, not determined.

‡Cells were washed and stained with FITC-labelled rabbit anti-human Ig.

§EBV-determined nuclear antigen, stained according to Reedman and Klein¹². Staining was 90–100% in all positive cultures.

||EP, LP, and SP are NNP-receptor positive lines established from three donors (E, L, and S) as described in the text. S(Unf) and E(Unf) are lines established from EBV infected unfractionated lymphocytes of donor S and E. L (Sup) is a line established from EBV infected lymphocytes, deprived of NNP-receptor positive cells. 'EP re-selected' is a line re-selected by NNP-erythrocyte rosetting of the EP line.

mycoplasma-free B95-8 cultures: 1 ml of the supernatant induced 20% EBNA positive cells in 10^6 cells of the BJAB line⁷ after 48 h incubation. As controls we infected either unfractionated lymphocytes from the same donor or the NNP-rosette-deprived fraction. The infected cells were incubated in RPMI-20% foetal calf serum, at 37°C, 5% CO₂. Permanent lines were established from all three donors after approximately 4 weeks. All viable cells of all lines were brilliantly EBNA positive and grew with a doubling time of approximately 24 h.

The established lines were tested for rosette formation and for plaque formation with NNP-coupled human erythrocytes⁸. The supernatants were assayed for specific NNP agglutination titre and for inhibition of plaque formation with 4-hydroxy-5-iodo-3-nitrophenacetic acid coupled T4 phage (NIP-cap-T4) (refs 9, 10). NIP show >90% cross

reactivity with the NNP-hapten¹¹. The immunoglobulin class of the product was assayed by sucrose gradient sedimentation and by incubating NNP-coupled erythrocytes in the supernatants from the different lines, followed by staining with FITC-labelled anti-human immunoglobulin sera.

As shown in Table 1, the cell lines derived from the EBV transformation of the NNP-rosetting fraction contained 13–18% NNP rosetting cells, whereas the lines derived from unfractionated cells or cells remaining in the supernatant after NNP rosetting gave no specific rosettes. EP line was re-selected by renewed rosetting. In this re-selected line, the frequency of the rosette forming cells rose to 86%. The same line also formed 69% NNP-specific plaques. Plaque formation was inhibited by sodium azide, confirming that it must have been due to active secretion. Since the frequency of plaque-forming cells nearly equalled the

*As in Table 1. ND, not determined.

†Aliquots of 0.1 ml of twofold dilutions of 0.22-µm filtered supernatants in BSS were mixed with 0.02 ml of 2% NNP-coupled erythrocytes. Agglutination was read after 60 min at 37°C. No agglutination was detected with uncoupled erythrocytes.

‡Aliquots of 0.3 ml of supernatant dilutions (filtered through 0.22-µm filter) were mixed with 0.3 ml of NIP-cap-T₄ suspension containing 200 PFU (plaque-forming units) and incubated for 4 h at 37°C. 5 ml 0.7% fluid agar containing about 10^8 *Escherichia coli* was then added, poured on to a solid 2% agar plate, and incubated overnight at 37°C. The titres shown are the reciprocals of the dilution causing 50% inactivation of haptenated phages.

§Supernatants were treated with 0.3 M 2-mercaptoethanol for 60 min at 37°C before mixing with the NIP-cap-T₄ phage.

||NNP-coupled erythrocytes were incubated with the culture supernatants for 60 min, at 37°C, washed and stained with FITC conjugated antisera. Uncoupled erythrocytes showed no staining after the same treatment. The following FITC conjugates were used: (1) rabbit anti-human IgG, IgA, IgM, kappa, lambda, (2) anti-IgM, specific for μ chains, (3) anti-IgG specific for Fc fragment; (4) anti-kappa, light chains (Bence-Jones); (5) anti-lambda, light chains (Bence-Jones). They were all products of Dakopatts, Denmark. The following cell lines were included as positive and negative controls in each test; BJAB¹⁴: IgM-kappa positive; Ramos¹⁴: IgM-lambda positive; Rael¹⁵: IgG-lambda positive.

Fig. 1 EP culture supernatant was run on 5–20% sucrose gradient, Beckman SV41 39,000 r.p.m. for 13 h. The fractions were tested for inhibition of NIP-cap-T₄ phage plaque formation on *E. coli* as described in Table 2. NIP shows >90% cross reactivity with the NNP hapten.

frequency of rosette-forming cells, the PFC and RFC forming populations were either identical or largely overlapping.

The agglutination titre of the supernatants ranged between 64 and 1,024. The 50% plaque inhibition titre with the NIP-cap-T₄ phage ranged between 86 and 4,070. All inhibitory activity was destroyed after treating the supernatant with 2-mercaptoethanol, indicating that the antibody was IgM, or at least not IgG.

Table 2 shows the results of all immunological tests, including staining of NNP-coupled erythrocytes with the culture supernatants, followed by FITC-conjugated anti-immunoglobulin reagents, as indicated. All three NNP-selected, transformed lines released anti-IgM-kappa antibody, according to the erythrocyte staining test.

Figure 1 shows a sucrose gradient pattern of the EP supernatant. It is clear that the specific plaque inhibition peaked at 19S. This is in line with the NNP-coupled erythrocyte staining test.

Since EBV-transformed lymphoblastoid cell lines are polyclonal for a long time after their establishment¹², the lines will have to be cloned before it is possible to say whether 100% antibody producing cells can be obtained in this way.

These results show that specific antibody-forming human cell lines can be established by a combination of B-lymphocyte selection, based on specific antigen affinity, and subsequent EBV immortalisation. It should be possible to manufacture lines, selected for the production of particularly interesting antibodies. Monospecific anti-HLA activity would be an obvious example.

Interferon-induced transfer of viral resistance between animal cells

MANY animal cell types exhibit the ability to communicate between themselves, both *in vivo* and *in vitro*¹. This phenomenon is thought to occur through gap junctions which allow cells to share their metabolites and small control molecules^{2–6}. The overall effect of this cellular communication seems to be a coordinated control of growth and function of different cells and cell types. Interferon is believed to act at the cell membrane in a fashion similar to polypeptide hormones^{7–9}. This membrane interaction in turn leads to de-repression and production of the antiviral protein^{10,11}. If, as is the case with polypeptide hormones¹², the induction of the antiviral protein is mediated through secondary molecules, these might influence adjacent cells. The presence of such intermediary molecules during interferon induction of the antiviral protein has been inferred from kinetic studies^{13,14}. The many instances of the species specificity of interferon action¹⁵ make this a testable hypothesis. We show here that cells made resistant to virus infection by treatment with their homologous interferon can transfer viral resistance to cells of a heterologous species insensitive to that interferon and also to cells of the homologous species.

The experimental plan was to determine whether interferon treated mouse L cells could transfer their antiviral resistance to co-cultivated heterologous cells. Mouse L cells were cultured in various ratios with either human (WISH) or baby hamster kidney (BHK) cells in the presence or absence of mouse C243 cell interferon. Controls consisted of an equivalent total number of either cell species alone in the presence or absence of mouse interferon.

Table 1 shows that whereas WISH or BHK cells alone are not sensitive to the action of mouse interferon, co-cultivation of these cells in the presence of mouse interferon and sensitive mouse L cells resulted in a marked inhibition of the expected yield of virus from the interferon-insensitive cells. Control cell mixtures, in the absence of interferon (Table 1, experiments 1 and 3), yielded at least the expected amount of virus as compared with virus yield from either cell type alone. These data indicate

Mouse L cells and human WISH cells or baby hamster kidney (BHK) cells in Eagle's medium (supplemented with 10% foetal calf serum) were cultured in various ratios in Micro Test II tissue-culture plates (Falcon Plastics, Oxnard, California). The total number of cells in each well (about 28 mm²) was 2.25×10^5 . Controls consisted of an equivalent total number of either cell species alone. Interferon (final concentration 7,500 PDD₅₀ U ml⁻¹) or an equal volume of medium was added; cultures were incubated overnight at 37 °C in a 4% CO₂ atmosphere. Supernatant fluids were decanted and each well infected with 5×10^4 p.f.u. of VSV. After 1.5 h at 37 °C, inoculum was decanted, cell sheets were washed once and replenished with fresh medium. Virus yields from pooled triplicate cultures were determined approximately 24 h later by a slightly modified microplaque assay in which methylcellulose (0.5%) was substituted for carboxymethylcellulose¹⁹. Since interferon-treated L cells produce a negligible amount of virus, the expected yield is calculated from the percentage of the WISH cells in a cell mix without interferon (experiments 1 and 3) or a percentage of the heterologous cell yield with interferon (experiment 2).

*The 50% plaque-depressing dose (PDD₅₀) is defined as the amount of an interferon preparation that inhibited 50% of the plaques from developing as compared with controls. In our assay system, i U of National Institutes of Health (NIH) mouse reference interferon preparation had a titre of 2 PDD₅₀ U.

†Any difference greater than 0.5 log₁₀ is significant at $P < 0.05$.

that the presence of interferon with its homologous cell can induce antiviral activity in heterologous cells. The controls show that inhibition of virus yield does not result from co-cultivation of different cell species but results from the presence of the mouse interferon preparation with the co-cultivated cells. In addition, the degree of inhibition of virus yield in mixed cultures in the presence of mouse interferon seems to be directly related to the ratio of L cells to WISH or BHK cells (Table 1, experiments 1 and 2); that is, the higher the proportion of L cells the more inhibition of virus yield from the heterologous cells.

Initially, it was important to determine that the observed transfer of viral resistance from L cells to heterologous cell species was initiated by mouse interferon and also that the transferred resistance had the characteristics of interferon action.

Table 2 shows that when partially purified mouse L-cell interferon, 100 PDD₅₀ U ml⁻¹ (10^7 U per mg protein), were incubated with a 1:1 mix of L and WISH cells there was 90% inhibition of the expected virus yield. Thus a partially purified interferon preparation caused transfer of resistance. Further, interferon produced by mouse L cells was as effective as that produced in C243 cells.

One hallmark of interferon action is its sensitivity to inhibition by actinomycin D. L cells were treated for 1 h at room temperature with actinomycin D $5 \mu\text{g ml}^{-1}$, washed to remove the unbound antibiotic and mixed with an equal number of untreated WISH cells in the presence or absence of mouse interferon. Control experiments had shown that actinomycin D $2 \mu\text{g ml}^{-1}$ caused 97% inhibition of RNA synthesis in 15 min. As seen in Table 2, actinomycin D blocked both the action of mouse interferon on L cells and the ability of L cells to transfer viral resistance to WISH cells.

Another criterion of interferon action is its inhibitory effect on a wide range of viruses. At the low multiplicity of infection (MOI) usually used, vaccinia virus was inhibited by mouse interferon in L cells alone (98.5%) as

well as in the 1:1 L cell: WISH cell mixture (93.3%) (Table 2). In higher MOI conditions (5×10^4 p.f.u. per well), vaccinia virus was not sensitive to mouse interferon in L cells alone, and transfer of resistance to WISH cells was not observed (data not shown). In our experience, therefore, the susceptibility of vaccinia virus to mouse interferon in L cells is highly dependent on the input MOI. Likewise, the ability of L cells to transfer viral resistance to WISH cells was similarly dependent on the input MOI. These data also show that interferon induced transfer of viral resistance can be demonstrated for both a DNA (vaccinia virus) and a RNA (vesicular stomatitis virus, VSV) virus in parallel with their sensitivity to interferon.

Taken together, Table 2 results strongly suggest that initiation of the transfer process was due to mouse interferon, since it occurred with crude as well as highly purified interferon preparations. Its action was on the cell rather than the virus, since resistance was manifested in the absence of interferon but in the presence of cells which had been acted on by interferon; and the transfer process was initiated by mouse interferon produced in two different cell lines (L and C243). These two interferon preparations have been shown to have all the classic characteristics of interferon (that is, species specificity, broad virus specificity, requirement of RNA and protein synthesis for action, inhibition by anti-mouse interferon antisera, non-dialysability, trypsin sensitivity, pH 2 resistance and so on)¹³. The results also indicate that transferred resistance has the characteristics of the interferon system in that it was blocked by actinomycin D, was effective against both a RNA (VSV) and a DNA (vaccinia virus) virus, and that the level of transferred resistance showed the same MOI dependency as resistance in the homologous cell.

If transfer of resistance is dependent on cell proximity, then the degree of transfer should be controlled by both the donor (L) to receptor (WISH or BHK) cell ratio (shown in Table 1) as well as the absolute cell density

Table 2 Characteristics of the transfer of viral resistance

*Statistical analysis was carried out using Students *t* test.

at a given ratio. To test the variable of cell concentration the effect of variation of cell density of a constant ratio of L and WISH cells was studied. Specifically, L and WISH cells each at a concentration of 1.5×10^6 cells ml^{-1} were serially diluted in twofold steps. L cells at each dilution were mixed 1 : 1 with WISH cells of the same dilution and the cell mixtures were plated in the presence or absence of mouse interferon ($7,500 \text{ PDD}_{50} \text{ U ml}^{-1}$). It was found that at an L cell-WISH cell ratio of 1 : 1, the demonstration of transfer of viral resistance was dependent on the absolute cell density (Fig. 1a). Interferon-induced transfer of viral resistance was not observed until the majority of cells were in close contact with neighbouring cells.

Since our initial experiments were carried out using very high levels of interferon ($100 \text{ PDD}_{50} \text{ U ml}^{-1}$), it was important to determine if transfer of viral resistance could be demonstrated at more physiological concentrations. Mouse L cells were cultured in a 1 : 1 ratio with WISH cells (cell number per well = 2.25×10^5) in the presence or absence (control) of different concentrations of mouse interferon or in its absence. Other controls consisted of an equivalent number of either cell type alone in the presence or absence of mouse interferon. Fig. 1b shows that transfer of viral resistance requires levels of interferon above $5 \text{ PDD}_{50} \text{ U ml}^{-1}$. Almost maximum transfer of attainable resistance can be demonstrated with $15 \text{ PDD}_{50} \text{ U ml}^{-1}$ of mouse interferon indicating that in the experimental conditions there is a limit to the degree of resistance which can be transferred. These data show that whereas transfer of viral resistance to heterologous cells requires more interferon than development of resistance in homologous cells the process is, nonetheless, fairly efficient in terms of the concentrations of interferon required. The concentrations of interferon necessary for transfer are well within physiological limits.

Although the exact mediator of the transfer of viral

resistance is unknown at present, it seems clear that it does not result from production of interferon by the heterologous cells in the mixture. The conclusion is based on two observations. First, interferon is thought to be externalised from a cell before acting¹⁶; however, in a mixture of 1 L : 1 WISH cell with mouse interferon, transfer of viral resistance occurred in the presence of antisera to human fibroblast interferon (enough to neutralise $300 \text{ PDD}_{50} \text{ U ml}^{-1}$ of any interferon which might be produced, data not shown). Second, transfer of viral resistance can occur from L cells to a line of African Green Monkey kidney cells (Vero) which have lost the ability to synthesise interferon (data not shown)¹⁷.

Another possibility is that human WISH cells are made sensitive to mouse interferon by co-cultivation with mouse L cells. Preliminary experiments indicate that this is probably not the case, since L cells treated with mouse interferon and washed extensively to remove the interferon can transfer resistance to WISH cells that are added after interferon have been removed (data not shown).

There are several implications of interferon-induced transfer of viral resistance between animal cells. First, some part(s) of the interferon system are apparently not 'species' specific because interferon-treated mouse L cells can transfer viral resistance to human WISH and baby hamster kidney cells. Second, the natural mechanism of interferon protection may include action on cells near the interferon-responding cell by means of this transfer mechanism. Such an idea has been proposed¹⁸ to explain the shallowness of the slopes of interferon dose-response curves¹⁸. This type of secondary action would amplify the efficiency of the interferon system. Third, since cell lines differ in the rate at which they develop resistance in response to interferon, one might expect in conditions of transfer of resistance in mixed populations of cells as occurs *in vivo*, more slowly responding cells might be influenced by cells which respond more rapidly to interferon. In other words, the rate of development of interferon-induced resistance in a mixed population of cells would be determined by the first responding cell type. In fact, in carefully controlled kinetic studies human WISH cells treated with $30 \text{ PDD}_{50} \text{ U ml}^{-1}$ human interferon developed significant resistance (50% inhibition of virus yield) to virus infection after 30 min treatment whereas human amnion U cells required 2.5 h to develop an equivalent degree (58% inhibition of virus yield) of resistance. When these two cell lines were mixed in a 1 : 1 ratio, the mixed population of cells developed significant viral resistance (63% inhibition of virus yield) after 30 min. That is, the mixed population assumed the kinetics of development of viral resistance of the more rapidly responding of the two cell types rather than an average (data not shown). This phenomenon would also tend to amplify the efficiency of the interferon system. Furthermore, this finding suggests that interferon-induced transfer of viral resistance occurs between cells of the same species and supports the notion of a function *in vivo* for transfer of viral resistance. A second example of homologous transfer of resistance is provided by our finding that interferon-treated L cells, which have been washed and treated with excess antiserum

Fig. 1 Effect of cell density (a) and interferon concentration (b) on transfer of viral resistance between L cells and WISH cells. Since interferon-treated L cells produce a negligible amount of virus, the percentage inhibition of expected virus yield is calculated by dividing the yield from an interferon-treated L cell-WISH cell mix (1 : 1) by half of the yield from a similar but untreated L cell-WISH cell mix, times 100.

to mouse interferon, can transfer viral resistance to untreated L cells (data not shown).

A fourth implication is that interferon-induced transfer of viral resistance may represent a system for studying transfer of biological activity between cells. Finally, the interaction of interferon at the cell surface may cause the formation of a chemical intermediate which is responsible for induction of the antiviral protein. Such a chemical mediator might be passed from cell to cell with a resultant transfer of viral resistance. Preliminary experiments have indicated that cell-free supernatant fluids from interferon-treated L cells can transfer viral resistance to human WISH cells. The elucidation of the nature of the mediator of transfer of viral resistance would greatly enhance our understanding of the induction process for the antiviral state. Should this mediator prove to be a simple molecule, the potential for control of viral infections is obvious.

In summary, we have shown that interferon-treated mouse L cells can transfer their antiviral resistance to co-cultured heterologous (human WISH or hamster BHK) cells which are insensitive to mouse interferon. Transfer of viral resistance seems to be initiated by interferon itself. Once transferred, the viral resistance has the characteristics of the interferon-induced antiviral state. The transferred resistance occurs between several cell species. The transfer of resistance depends on the ratio of cells homologous (to interferon) to cells which are heterologous as well as to the absolute cell density at a given ratio. The transfer process is efficient in that it requires relatively small amounts of interferon. Finally, we propose that this phenomenon is a natural process for amplification of the interferon system, and preliminary evidence indicates that it occurs by cell to cell transfer of an interferon-induced molecule.

Hyperacute autoimmune encephalomyelitis induced by a synthetic autoantigen

EXPERIMENTAL autoimmune encephalomyelitis (EAE) is an organ-specific autoimmune disease of the central nervous system (CNS) induced by immunisation with CNS tissue in

complete Freund's adjuvant (CFA). It is generally regarded as an animal model of acute disseminated encephalomyelitis. In Lewis rats a hyperacute variant of EAE can be induced using appropriate CNS immunogen with *Bordetella pertussis* vaccine as adjuvant with or without CFA¹⁻³. Hyperacute EAE (HEAE) differs from ordinary EAE clinically in its early onset and in its rapid and severe course, with high incidence of cerebral involvement and mortality. Histological lesions of HEAE are characterised by the presence in the CNS parenchyma of polymorphonuclear leukocytes, and necrosis, haemorrhage, oedema and fibrin^{1,2}. Because HEAE and ordinary EAE overlap histopathologically and immunologically³ they provide experimental evidence supporting the concept that certain human demyelinating diseases represent a spectrum of autoimmunity ranging from chronic multiple sclerosis to acute haemorrhagic necrotising leukoencephalopathy, for which HEAE is a model^{1,2,4}. We report here that the induction of HEAE is favoured by the absence of a methyl group in a sequence of 14 amino acids of the primary structure of the immunogen.

The autoantigen in CNS tissue which induces and is the target of the immune response in EAE is the basic protein of myelin. Few differences are found in the sequences of the approximately 170 amino acids of mammalian basic proteins which have been characterised (reviewed in ref. 5). Numerous encephalitogenic determinants have been identified in the basic protein molecule (reviewed in ref. 6). In contrast to the similarities in amino acid composition of their basic proteins, different species vary markedly in their susceptibility to EAE induction by defined peptide regions of the basic protein. For example, the major encephalitogenic determinant for guinea pigs is the 'tryptophan' peptide (residues 113-121) (ref. 7). That peptide also induces EAE in rabbits^{8,9}, but is inactive in rats⁹. Peptide 66-75 is encephalitogenic for rabbits¹⁰, but is inactive in rats¹¹, and a peptide comprising residues 70-88 of guinea pig basic protein is known to be encephalitogenic for rats¹²⁻¹⁴. With *B. pertussis* as adjuvant, we found that guinea pig basic protein was unique in its capacity to induce HEAE in rats when compared with basic proteins from seven other species⁵. We further established that the determinant of the guinea pig basic protein responsible for HEAE induction resided in the region 70-88 (ref. 12). We have now confirmed by synthesis that the unique antigenicity of the guinea pig basic protein leading to HEAE induction is determined by the primary amino acid sequence of a 14 amino acid peptide. The corresponding region of the rat basic protein, which differs by only a single amino acid substitution at residue 79 (threonine/serine), induces ordinary EAE but not HEAE.

Guinea pig and rat basic proteins were prepared from brain tissues⁵ and the corresponding midpeptides (residues 45-88) were isolated after 20 min of peptic digestion⁸. The midpeptides were further digested by rapid proteolysis with α -chymotrypsin (20-30 s at 37 °C). Preparative electrophoresis in pyridine-acetic acid-butanol-H₂O (1:1:2:36) yielded two fragments of 19 and 25 amino acids. Amino acid analyses identified the fragments as residues 70-88 and 45-69 respectively (Table 1). Peptide 73-86 (guinea pig sequence) was synthesised by the Merrifield solid phase technique.

Graded doses of basic proteins and peptides were prepared in saline, emulsified with CFA and injected intradermally into 10-week-old female Lewis rats as described previously³. *B. pertussis* vaccine (2×10^{10} organisms) was injected subcutaneously. Clinical signs of ordinary EAE and HEAE were scored daily. Ordinary EAE generally appeared around day 12 or later and consisted of flaccid weakness or paralysis of limbs and/or tail, and incontinence, and was usually not fatal. HEAE was readily distinguished from ordinary EAE clinically by the additional combination

HEAE was distinguished from ordinary EAE clinically by a combination of early onset (usually 9–10 d), rapid and severe course and high incidence of mortality and cerebral signs (irritability, seizures, coma and spasticity). Amino acid analyses were determined using a Beckman 121 analyser after hydrolysis for 24 h in 6 M HCl.

*Amino acid analysis: Phe (1.0), Gly (3.0), Ser (3.0) Asp (2.0) Arg (3.0), Ala (4.0), Pro (1.0), Lys (2.0), His (3.0), Thr (2.0), Tyr (1.0).

†The rat sequence (68–86) is identical to the guinea pig sequence (70–88) except for a threonine for serine substitution.

of early onset of signs (9–10 d), severe motor impairment with a high incidence of cerebral involvement (irritability, seizures, coma and spasticity) and a uniformly rapid and fatal course. Brains and spinal cords were examined histologically³.

Table 1 compares the encephalitogenicity of the whole guinea pig basic protein, its midpeptide (residues 45–88) and smaller fragments of that peptide. Doses as low as 0.17 nmol of guinea pig basic protein, 1.0 nmol of peptide 45–88 and 0.16 nmol of the chymotryptic fragment 70–88 induced HEAE. Ordinary EAE was induced by doses of peptide 70–88 as low as 0.0046 nmol. The larger chymo-

tryptic fragment 45–69 induced neither clinical nor histological signs of EAE at 5.5-nmol doses. The synthetic peptide comprising residues 73–86 induced HEAE (both clinical and histological signs (Fig. 1)) at a dose of 1.2 nmol.

Peptides corresponding to guinea pig residues 45–88 and 70–88, but derived from syngeneic rat basic protein, induced ordinary EAE, but not HEAE, when tested over a broad range of doses with identical adjuvants. Doses of 2.3 and 3.2 nmol induced very severe signs of ordinary EAE but cerebral signs were uncommon and most rats recovered. Thus the unique capacity of the guinea pig basic protein to induce HEAE (ref. 3) is not simply a dose effect but is determined by the amino acid sequence of the region 73–86. The only sequence difference in this region of the basic proteins of guinea pig (which induces HEAE) and rat (which induces only ordinary EAE even at high doses) is a serine/threonine substitution at residues 79. Thus the antigenic requirements for induction of two clinically distinct autoimmune syndromes are determined by one methyl group.

The fact that HEAE was induced by the synthetic peptide 73–86 rules out the possibility that the enzymatically derived guinea pig peptide might have been contaminated with another encephalitogenic fragment. Synthesis of additional analogues of the region comprised in residues 73–86 should allow definition of (1) the minimal antigenic requirements for induction of HEAE and (2) the essential difference between determinants inducing HEAE and ordinary EAE. The availability of defined synthetic autoantigens presents a unique opportunity to analyse the different immunopathogenic mechanisms involved in ordinary and hyperacute EAE.

Increased endoneurial fluid pressure in experimental lead neuropathy

THE endoneurial compartment of peripheral nerve is relatively inaccessible because of its small size and is maintained in a specialised environment by means of a perineurial barrier¹, a blood-nerve barrier² and a cerebrospinal fluid barrier. We have gained access to the endoneurial compartment of mammalian peripheral nerve by means of small polyethylene matrix (PEM) capsules and have recorded endoneurial fluid pressure (EFP) using an active servo null system³. The solid PEM capsules have pores of approximately 60 μ m which facilitate entry of fluid into the interstices and connecting polyethylene tubing, but unlike hollow capsules⁴, are not invaded by connective tissue. We have used PEM capsules to make serial measurements of EFP in control and lead-fed rats and watched the pathological changes. We did this because of the prominence of endoneurial oedema in, for example, inflammatory polyradiculoneuropathy⁵, diabetic neuropathy⁶, acromegalic neuropathy⁷ and experimental lead⁸ and galactose^{9,10} neuropathies, and because external pressure causes segmental demyelination and even axonal degeneration of peripheral nerve fibres¹¹. We found that EFP increased progressively in lead-fed rats and preceded the onset of fibre pathology. The time course of the increase and of fibre pathology suggests that increased EFP is a cause of segmental demyelination in lead neuropathy.

PEM capsules (external diameter 0.5 mm) tightly wedged in a PE-10 tubing were implanted into the left sciatic nerve of 18 Sprague-Dawley rats and EFP recordings were made 1 month later. Pressures from the capsules were measured using a modification of an active servo-null device originally developed by Wiederhielm¹². A micropipette containing hyperosmolar saline forms one arm of a balanced Wheatstone bridge adjusted for null. When the micropipette is wedged into a tubing connected to the capsule the EFP causes a shift in the fluid interface at the tip of the pipette, causing an error voltage. This voltage is amplified and applied to a bellows system which generates a counter-pressure within the pipette, restoring the fluid interface to its original position. The hydraulic pressure is measured with a transducer and recorded³.

After the initial recording nine rats were placed on a

Fig. 1 EFP does not change significantly with time in control rats (upper) but increases progressively in lead rats (lower). Arrow indicates onset of test feeding.

conventional diet to which 4% lead carbonate had been added (lead rats). The remaining nine animals were pair-fed the same diet but without the added lead (control rats). EFP recordings were repeated 3 weeks, 6 weeks, 3 months and 4.5 months after commencement of test feeding (Fig. 1). EFP recordings were successful in eight of nine control rats 1 month after implantation of the capsule and ranged from 0.5 to 1.8 mm Hg. They did not alter significantly in subsequent serial recordings. By contrast, the EFP was increased in seven of nine lead rats by 3 weeks after start of lead feeding and progressively increased in serial recordings (Fig. 1).

Three animals from each group were killed 3 weeks

Fig. 2 Transverse fascicular area of control (closed circles) and lead rats (open circles) at different times after start (arrow) of test feeding.

Fig. 3 Transverse section of peroneal nerve from control (upper) and lead rat (lower) after 3 months of lead feeding. Note the marked pericapillary and subperineurial oedema in the nerve of the lead rat.

and 3 months after start of test feeding and the remaining three controls and two lead rats (one meanwhile had died) were killed at 4.5 months. All morphological studies were done on the right peroneal nerve.

The transverse fascicular area (TFA) of right peroneal nerve was digitised on photographic enlargements ($\times 230$) of transverse sections of nerves embedded in Epon. The TFA was increased at 4½ months after test feeding and was variably increased even earlier in lead rats (Fig. 2). The number of measurements were small but the trend paralleled that of EFP recordings.

On pathological evaluation, endoneurial oedema was absent or mild at 3 weeks and prominent by 3 months. Oedema tended to be most pronounced around small blood vessels and in the subperineurial area (Fig. 3). Fibre pathology, as assessed by phase contrast microscopy of sections and by evaluation of teased fibres (100 fibres per nerve) consisted chiefly of segmental demyelination and remyelination. Axonal degeneration was uncommon. In Table 1 fibres showing segmental demyelination with or without regeneration are grouped under percentage demyelination. Segmental demyelination was not found in nerves of control rats or in nerves of rats fed lead for 3 weeks. At 3 months, however, segmental demyelination was seen in all lead rats and the changes were marked by 4½ months (Table 1).

Our study provides the first evidence that endoneurial pressure is increased in a neuropathy. The rise in EFP in experimental lead neuropathy is small in absolute terms and relative to the externally applied pressures which have been used to produce segmental demyelination^{11,13}; however, the relative increase above baseline values is considerable. The

mean EFP after 6 weeks of lead feeding is approximately four times and at 3 months six times baseline values. Moreover, the mode of action of experimental compression is mechanical¹⁴ and acute, compression being applied for minutes to an hour or two, whereas the pressure rise in experimental lead neuropathy as reported here is maintained over months. The magnitude of the increase in pressure is not sufficient to collapse endoneurial and perineurial capillaries¹⁵ so that ischaemia from capillary collapse, as was postulated by Sunderland¹⁶ for median nerve entrapment in man, should not be the mechanism of segmental demyelination in this model.

Development-related changes of triiodothyronine binding to brain cytosol receptors

SEVERAL lines of evidence have established that thyroid hormones have a major role in the functional differentiation of the mammalian central nervous system^{1–4}. Clinical or experimental hypothyroidism in early life results in behavioural disturbances and mental dysfunction which are apparently the outward manifestation of well-defined biochemical and structural lesions observed in the cerebellum and cerebral cortex of experimental animals. Significantly, the defects arising from the hypothyroid state are amenable to hormone therapy only during an early critical age period. Furthermore, unlike the liver and most other tissues, the mature brain is not responsive to the manipulation of the thyroid hormone state at least in terms of certain biochemical parameters. The brain is thus uniquely dependent on thyroid hormones for the full expression of functional development during a limited age period which is analogous to the situation in amphibian metamorphosis⁵. I reasoned that the acquisition and disappearance of brain sensitivity to thyroid hormones may be related to their binding properties with cellular receptors. I show here that the affinity of rat brain (cerebellum) cytosol for triiodothyronine (T_3) is high during an early age period when cytodifferentiation is most intense and declines dramatically with age with no apparent change in the number of binding sites. In sharp contrast, the liver shows a marked increase in the number of binding sites with age with little change in affinity.

The rat cerebellum was chosen for study since both the structural and functional differentiation of this region at an early age and its responsiveness to the thyroid hormones

Fig. 1 Scatchard analysis of binding of $^{125}\text{I}-T_3$ to cytosol prepared from rat (a) cerebellum and (b) liver at 10 (\square), 20 (\circ) and 50 (\times) days of age. Cytosol (100–150 μg protein) was incubated with increasing concentrations of $^{125}\text{I}-T_3$ (4×10^{-10} to 1×10^{-8} M, final concentration) for 2 h at 0°C . Bound hormone was separated from free hormone by the addition of 0.2 ml of a dextran-coated charcoal suspension (5% charcoal: 1% dextran of molecular weight 60,000–90,000 in 20 mM Tris-HCl, pH 7.8). The tubes were vortexed for 6 s, kept on ice for 10 min and centrifuged at 4000g for 10 min. A portion of the clear supernatant containing the bound $^{125}\text{I}-T_3$ was rapidly removed and counted in a Packard Auto-gamma spectrometer. Sephadex G25 chromatography²¹ of the bound fraction confirmed that 94% of the radioactivity was in the form of T_3 . The magnitude of the high affinity, saturable binding was estimated by subtraction of the radioactivity bound in the presence of a 1,000-fold molar excess of native T_3 . The free hormone concentration was calculated by subtraction of the total $^{125}\text{I}-T_3$ bound from the total $^{125}\text{I}-T_3$ added per assay and expressed as nmol per l of cytosol. The dextran-coated charcoal procedure removed more than 98% of the $^{125}\text{I}-T_3$ at all concentrations in the absence of cytosol. The removal of the bound hormone by Sephadex G25 gel filtration gave comparable results with the charcoal procedure. The values are means of two determinations which did not differ by more than 3% from the mean. The values are not corrected for the dissociation of the bound hormone in the presence of charcoal.

during this period have been extensively characterised. Cytosol was prepared from the cerebellum and liver (perfused through the portal vein with 25 mM KH_2PO_4 , 0.1 M NaCl, pH 7.4) of 10-, 20- and 50-d old Sprague-Dawley rats. The tissues were homogenised with a motorised Teflon pestle in 5 volumes of 0.32 M sucrose, 20 mM Tris, 1.0 mM MgCl_2 (pH 7.6). After removal of the mitochondrial fraction by centrifugation in the cold at 12,000g for 20 min, the supernatant was centrifuged at 130,000g for 90 min at 4°C . The supernatant, which represented the cytosol, was aspirated (excluding the surface lipid in the case of the

liver) and stored in small portions at -20°C for no longer than 2 weeks. Cytosol, equivalent to 100–150 μg protein was incubated in the presence of $^{125}\text{I}-T_3$ (specific activity 290 Ci mmol^{-1} , Abbott) in 12 \times 75-mm polypropylene tubes for 2 h at 0°C in a final volume of 0.5 ml. The reaction medium contained 0.25 M sucrose, 20 mM Tris, 1.0 mM MgCl_2 , 1 mM dithiothreitol and 5% glycerol (pH 7.6) and was used for the dilution of cytosol and labelled and unlabelled hormones. The presence of dithiothreitol was found to be necessary for maximal binding and glycerol was included to prevent receptor decay particularly over long incubation intervals. A second identical series of tubes contained, in addition, 1,000-fold molar excess of unlabelled T_3 as a competitor for high affinity (saturable) $^{125}\text{I}-T_3$ binding. $^{125}\text{I}-T_3$ was at least 92% pure as determined by thin-layer chromatography. The level of cytosol protein as used in the assay was within the range where binding was directly proportional to protein for all age groups.

Representative Scatchard plots of the binding of increasing concentrations of $^{125}\text{I}-T_3$ to cerebellar and liver cytosol during development are shown in Fig. 1a and b, respectively. Saturation was achieved with about 1×10^{-8} M T_3 at all ages. The binding parameters, affinity constant and maximum binding capacity, derived from these curves are listed in Table 1. The striking decline in the affinity constant for the cerebellum with age apparently correlates with the limited period of responsiveness of the brain to thyroid hormones during and early critical period of development. In the liver, on the other hand, which does not demonstrate an age-dependent tissue sensitivity to thyroid hormones, the number of binding sites increases markedly with age with little change in the affinity constant.

The development of the cerebellar cortical architecture in the rat is almost exclusively confined to the first 3 weeks of life and the sequence of events have been clearly documented⁸. These maturational processes are dependent on the presence of thyroid hormones; thus, neonatal hypothyroidism retards cellular proliferation and differentiation and impairs the growth of neuronal processes, the formation of synapses and their organisation⁷⁻⁹. Physiological levels of hormone are capable of reversing these aberrant changes if administered at an early age¹⁰.

It is significant that the affinity constant for the cerebellum is high at an age when cellular proliferation and migration are maximal and cytodifferentiation is proceeding rapidly. This relationship implies that the regulation of gene expression may come under hormonal control. Evidence that thyroid hormones bind to nuclear receptors with high affinity in several tissues, including brain¹¹⁻¹³, provides support for this contention.

The significance of recognition sites for T_3 in brain cytosol shown here and earlier in several mammalian non-neuronal tissues^{12,16-22}, is not clear. The T_3 binding characteristics in cytosol seem to be considerably different from nuclear preparations^{17,19}. Moreover, unlike steroid hormones, cytosol binding is apparently not a prerequisite for the interaction of thyroid hormones with nuclear re-

Table 1 Association constants (K_a) and maximal binding capacity (M) of cerebellum and liver during development

Tissue	Age (d)	K_a (l per mol $\times 10^{-7}$)	M (pmol per mg protein)

ceptors^{11,13,14,17}. Cytosol binding sites may serve to provide a readily available supply of hormone for biological action at some additional intracellular site and thus may be regarded as 'acceptors'. Alternatively, cytosol binding sites may indeed be regarded as one of several primary receptors in accordance with the multiple actions of thyroid hormones.

Axonal accessibility and adaptation to osmotic stress in an extreme osmoconformer

It is generally assumed that neuronal function is critically dependent on a relatively stable chemical environment. In most animals investigated homeostasis of the neuronal microenvironment is achieved by regulation of the chemical composition of the body fluids and, in higher vertebrates^{1–3} and insects⁴, by additional homeostatic control within the nervous system. The axons of an extreme invertebrate osmoconformer⁵ (the worm *Mercierella enigmatica* Fauvel) have been shown, however, to adapt and to continue to produce sodium-dependent action potentials when exposed to massive blood dilution^{6,7}. It has also been suggested that short-term protection is provided by a facultative blood-brain barrier which enables the axons to adapt relatively slowly to hyposmotic stress⁷. We now report that the effects of isosmotic and hyposmotic dilution of the surrounding medium on the giant axons of *Mercierella* are direct, and that axons respond rapidly to changes in ionic concentration and adapt to extreme osmotic stress almost immediately.

Electron microscopy showed that the giant axon is overlaid by narrow glial processes which form an incomplete investment. Where the covering is more complete the intercellular clefts which link the extra-axonal fluid with the

Fig. 1 *a*, Giant axon (GA) and surrounding tissue of an animal adapted to seawater showing penetration of lanthanum through the glial clefts to the axon surface. Animals were incubated for 30 min in normal saline with 10 mM LaCl_3 added before fixation by the method devised by Baskin⁸ ($\times 20,500$). *b*, Small axons from the connective of a seawater-adapted animal exposed briefly to dilute saline, a treatment previously supposed to limit access to the axon surface. Lanthanum is shown here to penetrate to the intercellular spaces between the axons. Animals briefly exposed to dilute saline were incubated in 50 mM LaCl_3 for 2 h before fixation with glutaraldehyde in dilute saline, enriched with phosphate to a final concentration of 0.05 M and with added calcium. The preparation was post-osmicated and stained *en bloc* with uranyl acetate ($\times 31,000$).

blood, or bathing medium, do not seem to be occluded by junctional complexes.

Externally-applied lanthanum was found to penetrate to the axon surfaces in seawater-adapted individuals bathed in normal (Fig. 1*a*) and diluted (10%) physiological saline (Fig. 1*b*). There is therefore no ultrastructural evidence for a significant restriction of intercellular diffusion to the axon surface in hyposmotic conditions.

We also found that the axonal responses to hyposmotic solutions depend on the method of dilution of the fluid in the recording chamber. With continuously flowing saline, as used before⁷, the lack of effect of rapid hyposmotic dilution resulted from fluid stratification which produced an unstirred layer of relatively high salinity in the immediate vicinity of the axon. When hyposmotic dilution was achieved by vigorously syringing the solution directly on to the preparation, relatively rapid axonal responses to ionic dilution could be observed in isosmotic and hyposmotic conditions (Fig. 2).

Our results indicate that the giant axon of *Mercierella* is not structurally protected from the immediate effects of hyposmotic stress. Even if some protection is provided in the intact animal by fluid stratification in the immediate vicinity of the axon surface, the giant axon can adapt to hyposmotic stress in experimental conditions much more rapidly than has been previously supposed⁷.

Intact colonies of *Mercierella* can function normally in distilled water for several weeks. Fig. 3*b* and *c* illustrates the

Fig. 2 Effects of 50% dilution of the physiological saline (1,024 mOsm) on the action and resting potentials, recorded with a conventional intracellular microelectrode (40 M Ω), in a giant axon of *Meiclerella*. Hypoosmotic saline was made by diluting standard saline with distilled water. Isosmotic dilution was achieved by addition of mannitol to diluted standard saline. In these experiments the solutions were syringed (at a rate of 0.5 ml s⁻¹) directly on to the preparation. The standard saline was based on the ionic and osmotic concentrations of seawater-adapted animals (mM: Na⁺, 482.3; K⁺, 30; Mg²⁺, 77; Ca²⁺, 31, SO₄²⁻, 26; Cl⁻, 663.8; OH⁻, 12.5 and PIPES, 7.5 mM).

responses of the giant axon to a dilution regime (Fig. 3a) similar to that in the blood of intact animals after transfer of a colony from seawater to distilled water. In spite of extreme osmotic stress, action potentials persisted throughout the experiment, with some diminution in amplitude only during the initial period of dilution. The hypoosmotically-

Fig. 3 Effects of progressive hypoosmotic dilution on the resting and action potentials in a giant axon of *Meiclerella a*. The broken line illustrates the rate of dilution of the blood measured on transfer of colonies of *Meiclerella* from seawater to distilled water⁵. The continuous line indicates the step changes in dilution used in this experiment. **b**, Continuous recording of the resting and action potentials recorded by a transient signal processor and displayed on a chart recorder. **c**, Action potentials at different stages of hypoosmotic adaptation.

adapted action potentials were of larger amplitude than those recorded initially in full strength saline. As shown from axons from individuals which were hypoosmotically adapted in distilled water for several weeks⁷, the *in vitro* adaptation involves a relatively slow hyperpolarisation of the axon membrane. This, together with an apparent reduction in intracellular sodium concentration⁷, facilitates overshooting action potentials of large amplitude in the face of the extreme dilution of the ionic and osmotic concentration of the bathing medium.

These observations indicate that the giant axons in this euryhaline osmoconformer can withstand and adapt to extreme changes in the osmotic and ionic composition of its immediate fluid environment. This establishes the important principle that neuronal homeostasis can be achieved not only by regulation of the extracellular fluid (as in higher vertebrates and insects) but also by relatively rapid adaptations by the nerve cells themselves.

Modification of synaptic input following unilateral labyrinthectomy

UNILATERAL vestibular nerve transection is followed by postural and locomotor disturbances that disappear to a large extent with time after the lesion¹. This compensation requires a central readjustment of the tonic and phasic output from the remaining vestibular apparatus to the motor nuclei involved in the control of limb and head muscles. To study the mechanisms of this type of motor learning at the single neurone level, we have used the frog (*Rana temporaria*), because in this species the time course of the postural compensation following hemilabyrinthectomy has been thoroughly studied². Furthermore, the synaptic circuitry and functional organisation of the peripheral and central vestibular systems are well known for this species³. Since the vestibular nuclei are the first integrative structures in which bilateral vestibular and other sensory inputs converge, and since their output influences motor systems directly or indirectly, we began to look for plastic changes in second order vestibular neurones. Many of these neurones are monosynaptically excited from the ipsilateral⁴ and disynaptically through commissural fibres from the contralateral⁵ labyrinth.

After unilateral labyrinthectomy via a ventral, extracranial approach, acutely (≤ 12 h) and chronically (≥ 60 d) deafferented vestibular neurones were activated by electrical stimulation of the anterior branch of the intact contralateral VIIIth nerve. Dissection, stimulation, and recording procedures were as described previously^{4,5}. Synaptic potentials were averaged with a Nicolet computer and corrected for the extracellularly recorded field potential⁶. Duration of excitatory postsynaptic potentials (e.p.s.ps) were measured at half amplitudes and the times-to-peak from the points of divergence of the intra- and extracellular records to the peak of the e.p.s.ps. To facilitate comparison of amplitudes, threshold values, and shape indices

of e.p.s.ps⁷ amongst different animals, the stimulation intensity was expressed in multiples of the N_1 field potential threshold (T_{N_1}) recorded in the ipsilateral vestibular nucleus⁴ and was restricted to $\leq 5 \times T_{N_1}$.

In acutely operated animals stimulation of the intact VIIIth nerve elicited field potentials in the vestibular nuclei on both sides (Fig. 1A) as described previously⁴. The presence of these field potentials served as a convenient measure of electrode location and the state of the animal.

Intracellular recordings from vestibular neurones located ipsi- and contralaterally to the stimulation side revealed e.p.s.ps with significant differences in their shape indices (Fig. 1B). The e.p.s.ps elicited from primary afferent fibres had a much greater amplitude (2.6 ± 1.0 mV; $n = 45$) and a much shorter time-to-peak (4.2 ± 1.6 ms; Fig. 2) than those elicited through commissural fibres (1.6 ± 1.1 mV; $P < 0.001$ and 12.4 ± 3.2 ms; $P < 0.001$; $n = 75$; Fig. 2). With increasing stimulus intensity, the time-to-peak of the e.p.s.ps did not shorten systematically. The duration of the e.p.s.ps was in general about three times the time-to-peak but was often much longer because of the arrival of late polysynaptic potentials. The e.p.s.ps induced by primary afferent fibres regularly triggered bursts of partial⁴ and full action potentials whereas e.p.s.ps induced by commissural fibres elicited single spikes in only 22.1% and repetitive firing in only 2.6% of the cells. The slower time-to-peak and the lower efficacy of commissural e.p.s.ps to provoke action potentials fully corroborate the suggestion⁵ that commissural fibres form synapses more peripherally on the dendrites of vestibular neurones than primary afferent fibres which are known to synapse on and close to the soma⁸.

In chronic animals the vestibular-evoked field potentials

Fig. 1 A, Field potentials in the vestibular nucleus recorded on the ipsilateral sides (1) and contralateral (2, 3, 4) to VIIIth nerve stimulation from an acutely (2) and a chronically (1, 3, 4) operated animal. The presynaptic components (arrows) indicate the arrival of impulses in primary afferent (1) and in commissural fibres (2, 3) respectively. Cutting the vestibular commissure abolished both the prepotentials as well as the later slow negative field potentials (4) recorded previously at the same depth (500 μ m, 3) but left the ipsilateral field potential (1) unchanged. The depth profiles of the slow negative field potentials of acute and chronic animals were similar (maximal response 450–500 μ m), but their amplitudes were different (compare 2 with 3). Calibration pulse: 0.5 mV; 1 ms, positivity upwards. B, E.p.s.ps recorded in vestibular neurones were induced by primary afferent fibres (a) and by commissural fibres (b, c). b, was recorded in an acutely and c in a chronically deafferented neurone. Note the shorter time-to-peak and the larger amplitude of c in comparison with b. Traces are redrawn from the computer-averaged e.p.s.ps (16 sweeps) and were superimposed at the point of their onset. Downward artefacts represent stimulation; calibration pulse: +1 mV; 1 ms.

recorded in the deafferented vestibular nucleus (Fig. 1A) were of larger amplitude (two to three times) than those recorded in acute animals. Usually bursts of evoked spikes were superimposed on the field potential, a finding which was rarely observed in intact⁵ or in acute animals from this series of experiments. In chronic preparations, in contrast to acute animals, many vestibular neurones were spontaneously active with firing rates (1–10 Hz) similar to those recorded on the intact side.

The increased excitability of deafferented vestibular neurones might have been caused by a change in the excitability of vestibular neurones located on the intact side which project to the deafferented nucleus. To investigate this possibility, we recorded extra- and intra-axonally from commissural fibres on the lesioned side of acute and chronic animals as well as in the depth of the brainstem where these fibres are known to cross⁹. A comparison of the data obtained in these two groups of experimental animals showed practically identical values for the thresholds of single spikes ($1.6 \times T_{N_1}$), bursts ($2.3 \times T_{N_1}$) and for the number of spikes per burst (2.9) as well as for the inter-spike interval (2.4 ms). These findings indicate that the excitability and the output pattern of vestibular neurones on the intact side have not changed postoperatively.

Intracellular recordings from vestibular neurones on the chronically deafferented side (Fig. 1B) showed that they receive predominantly excitatory inputs from vestibular commissural fibres as in intact animals⁶. The major characteristics of commissurally evoked e.p.s.ps from acute and chronic animals are compared in Table 1. As can be seen, e.p.s.ps in both groups of animals had similar thresholds and latencies. In chronic frogs, however, the amplitude of the evoked e.p.s.ps was significantly larger, and generated in many more cells partial and full action potentials at a significantly lower stimulus intensity than in acutely operated or intact animals⁶. The rise time of the e.p.s.ps was also significantly shorter in chronic than in acute animals (Fig. 2) and varied only a little (± 1.5 ms) with increasing stimulus intensity. The duration of the e.p.s.ps varied greatly, but many of the e.p.s.ps recorded in chronic animals with a shorter time-to-peak had a longer duration. In addition polysynaptic components of the e.p.s.ps could prolong the falling phase considerably.

The changes in e.p.s.p shape indices and spike thresholds were observed in chronically deafferented neurones in spite of the absence of changes in threshold and bursting pattern of commissural input fibres. This indicates that the higher synaptic efficacy of the crossed excitatory input must be produced on the deafferented side somewhere between commissural terminals and postsynaptic neurones. One possible mechanism that could explain all of the observed changes in e.p.s.p. parameters would be axonal sprouting of commissural terminals resulting in the formation of new functional synapses on the vacated space on soma and proximal dendrites of vestibular neurones. As a result of the cable properties of dendrites⁷, these mixed den-

Fig. 2 Distribution of times-to-peak of e.p.s.ps in acutely (a) and chronically (b) deafferented second-order vestibular neurones. The e.p.s.ps elicited from primary afferent fibres (cross-hatched bars) have a much shorter rise time than those elicited from commissural fibres. After chronic deafferentation the same commissural input induces e.p.s.ps with a significantly shorter rise time (b).

dritic-somatic e.p.s.ps would be less attenuated in their rise times and amplitudes and, therefore, more effective in driving the cell. Similar changes in the shape indices of e.p.s.ps have been observed in other partially deafferented nuclei¹⁰ where sprouting was shown to occur¹¹. Another mechanism, for example, increased chemosensitivity of the denervated neurones to a given transmitter, is unlikely since the time-to-peak of the response does not seem to be affected¹². Also, neither the ipsilateral nor the contralateral group of e.p.s.ps showed systematic shortening of the time-to-peak with increasing stimulus intensity. Changes in passive membrane properties, although not excluded, cannot explain all the alterations observed.

The increase in excitatory synaptic efficacy of the commissural system may provide part of the background activation of chronically deafferented vestibular neurones necessary to counterbalance the asymmetry in the output of the two vestibular nuclei at rest. As a result of this newly acquired symmetrical output, the animals will resume their normal pose. Furthermore, the enhanced crossed excitation will also be of use for dynamic postural reflexes requiring a symmetrical output to somatic motoneurones. To obtain functional recovery of all vestibular reflexes, crossed inhibitory mechanisms must also be postulated¹³; these will be subject of a later report.

Enkephalin effects on release of brain acetylcholine

MORPHINE and other narcotic analgesics depress the spontaneous release of acetylcholine (ACh) from the rat cerebral cortex *in vivo*^{1,2}. The effect of these agents on the central release of ACh, like their inhibitory effects on the peripheral release of ACh in the guinea pig ileum, is stereospecific³ and can be fully antagonised by naloxone⁴. It is well recognised that the endogenous opiate peptides, enkephalins^{5,6} and endorphins⁷, depress the output of ACh from the electrically stimulated guinea pig ileum by a specific action on opiate receptors. This suggests that in the central nervous system endogenous opiates may exert a significant influence on the release of ACh. We have examined the effects of two enkephalins, methionine-enkephalin (Met-enkephalin) and leucine-enkephalin (Leu-enkephalin) on the cortical release of ACh *in vivo* following intraventricular injections. Our observations show that natural enkephalins may interact with opiate receptors in the brain to modulate the release of ACh from the cholinergic neurones.

Experiments were carried out on Sprague-Dawley rats (250–300 g), lightly anaesthetised with a pentobarbital-urethane mixture. The spontaneous release of cortical ACh, which occurs in the presence of neostigmine (50 $\mu\text{g ml}^{-1}$), and atropine (0.5 $\mu\text{g ml}^{-1}$), was measured using the cup technique of MacIntosh and Oborin⁸. Experimental details of this procedure in rats, and the estimation of ACh, have been described elsewhere^{2,4}. In this study, the collection periods for cortical ACh release were shortened to 10 min from the 20–30 min used in earlier tests. The samples of cortical fluid (0.2 ml each) were collected bilaterally and both samples were pooled before estimation of ACh. The peptides, in most experiments, were administered by intraventricular (i.v.t.) injection through a fine cannula placed in the lateral ventricle on the left side. In a few tests with Met-enkephalin, the intravenous (i.v.) route of administration was used. Naloxone was always administered by i.v. injection through a femoral catheter.

Met-enkephalin (20 μg) depressed the release of ACh during the first 10-min collection period after a single i.v.t. injection. Recovery of release to pre-injection levels occurred after about 50 min. When administered intravenously Met-enkephalin (2.5 mg per kg) was completely ineffective. In subsequent experiments effects of both Met-enkephalin and Leu-enkephalin on ACh release were investigated, and in these tests naloxone was administered to animals during the peptide-induced response. As shown in Fig. 1a and b, both enkephalins depressed ACh release to the same degree and their effect was fully reversed by naloxone. When administered before enkephalins, naloxone completely blocked the inhibitory effect of enkephalins on ACh release (Fig. 1c and d). In previous work with morphine, both depressant and stimulant effects on central ACh release have been reported^{9,10}. In some cases low doses of opiates depress central ACh release while higher doses enhance this release^{3,10}. To observe if enkephalin has a dual action on release, effects of several doses of Met-enkephalin on cortical ACh release were tested. Met-enkephalin produced only a dose-related inhibition of ACh release (Fig. 2). The inhibition produced by lower doses of

Met-enkephalin was fully reversed by naloxone when it was injected after the peptide, but the inhibition produced by larger doses was only partially reversed by the antagonist (Fig. 2).

Our findings show that both Met-enkephalin and Leu-enkephalin inhibit the spontaneous release of ACh from the cerebral cortex *in vivo*. The fact that their effect could be antagonised by the specific opiate antagonist naloxone suggests that these enkephalins are acting selectively on opiate receptors to influence the release of cortical ACh. In the guinea pig ileum⁸, and the opiate receptor binding assay¹¹, Met-enkephalin is twice as potent as Leu-enkephalin. As only one dose (10 µg) of Leu-enkephalin was tested here, no definite conclusion can be drawn regarding the potency of action of two enkephalins on the central ACh release. At this dose, however, the effects of Met-enkephalin and Leu-enkephalin on ACh release were very similar and their action was completely blocked by naloxone. In previous work with opiate analgesics we have observed that when naloxone is administered after morphine-induced depression of ACh release, it produces a rebound effect on this release⁴. The post-naloxone level of output in such tests greatly exceeds the pre-drug control level^{3,4}. Interestingly, no rebound effect could be observed when naloxone was given after the enkephalin induced depression. Furthermore, we did not observe the enhancement of ACh release by opiates which has been reported in certain circumstances^{3,9,10}. Further investigation is necessary to clarify the basis for differences between the action of opiate analgesics and opiate peptides. In this regard the use of more stable analogues of enkephalins, endorphins or agents which inhibit the degradation of natural enkephalins may prove useful.

Naloxone administered by itself enhances the electrically

Fig. 1 Inhibitory effect of (a), Met-enkephalin and (b), Leu-enkephalin on the release of ACh from the intact rat cerebral cortex. The antagonism of the effect of (c) Met-enkephalin and (d) Leu-enkephalin by pretreatment with naloxone (Nal). Enkephalins were administered by intraventricular injection in a 10 µl volume, and naloxone was given intravenously in all experiments. Control release represents average release of ACh during two collections preceding the first injection. Mean \pm s.e.m. of 3–6 experiments is shown.

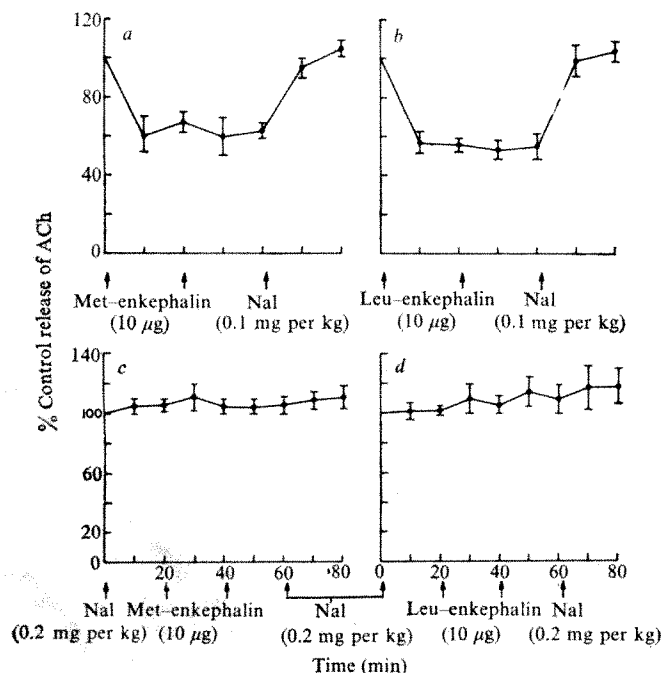

Fig. 2 Inhibition of cortical ACh release by several doses of Met-enkephalin, and the reversal of this inhibition by naloxone. ○, represents the release of ACh 10 min after intraventricular injection of Met-enkephalin; ●, represents release of ACh 10 min after intravenous injection of naloxone in the same animal. A separate group of animals was used for each dose of Met-enkephalin. Mean \pm s.e.m. of 3–4 experiments is shown.

stimulated release of ACh from the rat cortex⁴, and it has been suggested that this facilitatory effect of naloxone may be due to the antagonism of an endogenous opiate released by stimulation. This suggestion is strengthened by this demonstration of an inhibitory action of enkephalins on ACh release. Other investigators have reported an inhibition of noradrenaline¹² and dopamine¹³ release from brain slices by endogenous opioid peptides. In view of these reports, and present findings in an *in vivo* model of ACh release, an attractive suggestion is that the enkephalins or endorphins in the central nervous system may serve to modulate the release of neurotransmitters resulting from activity in the catecholaminergic and cholinergic pathways.

Polymerising ability of C₆ glial cell microtubule protein decays much faster than its colchicine-binding activity

BECAUSE of its high degree of specificity¹, the binding of colchicine to tubulin has become a powerful tool for the quantification and subcellular localisation of the protein. The mechanism of the binding reaction is not yet completely understood, but several of its characteristics are well documented. One of these is the decay of binding capacity with time, which follows the kinetics of a first-order reaction^{2,3} and is accentuated at elevated temperatures⁴. Although correlation between this rate of decay and the loss of other characteristic functions of tubulin, such as its ability to polymerise into microtubules, has not been directly established by experiment, carefully controlled measurements of the decay of colchicine binding seem to be useful for estimating the stability of the tubulin molecules *per se*. In contrast, the decay rate of the polymerisability of tubulin preparations should depend not only on the stability of the tubulin molecules themselves but also on that of other factors that may be essential for polymerisation⁵⁻⁷. As part of our recently initiated^{8,9} attempt to study the mechanisms regulating microtubule assembly in cultured cells, we report here that tubulin preparations from rat glial C₆ cells exhibit a decay rate of colchicine-binding activity that is quite different from the decay rate of polymerisability.

Tubulin preparations purified from crude cell extracts by one cycle of *in vitro* polymerisation (with 4 M glycerol) and depolymerisation^{8,10}, which by SDS-gel electrophoresis scans contained about 70% tubulin, were used in time course studies of both the capacity to bind colchicine and the ability to polymerise. The depolymerisation was carried out by suspending the tubulin pellet in glycerol-free buffer, since the stabilising effect of this reagent on polymerisability¹⁰ and possibly on colchicine-binding activity¹¹, might have obscured the results. The decay rates of colchicine-binding activity were determined by pre-incubation of sample aliquots at 37 °C for various lengths of time before assaying the binding of ³H-colchicine¹. The results of such an experiment, carried out with purified C₆ tubulin, are shown in Fig. 1. Typically, the binding activity decayed in an apparent first-order manner with a half life of 230 ± 37 min. In the same conditions, hog brain tubulin (three polymerisation cycles) had a half life of 293 ± 20 min. Purification of the C₆ tubulin by repeated cycles of polymerisation had no effect, within experimental error, on the kinetics of decay.

In other studies (G.W., L.S.H. and R.D.C., unpublished), it was found that *in vitro* microtubule formation from depolymerised C₆ tubulin is very similar to that of hog brain tubulin in that alike polymeric intermediates in the form of rings and planar and twisted ribbons are observed. The occurrence of such structures during the assembly of microtubules from hog brain tubulin has been studied extensively¹²⁻¹⁴. The decay rate of the polymerisability of depolymerised C₆ tubulin preparations may be determined directly, by measuring from electron micrographs¹² the total amount of polymer, that is, ribbons and tubules, that formed after incubation at 37 °C after various time intervals, following the last cold spin, at 0 °C. Monitoring assembly by quantitative electron microscopy has the advantage of allowing a distinction to be made between these ordered tubulin polymers and amorphous tubulin aggregates which affect measurements made by light scattering or viscometry. Throughout this study the incubation periods at 37 °C extended beyond the time during which ring structures could still be observed. The

Fig. 1 Decay rate of colchicine-binding activity. $t_{1/2} = 230 \pm 37$ min. Rat glial cells (clone C₆)⁸ were grown suspended in Minimal Essential Medium (Joklik-Modified, No. F-13, Grand Island Biological, Grand Island, New York), supplemented with 5% calf serum, to a final density of approximately 1×10^8 cells ml⁻¹, and collected by centrifugation at 700g for 10 min at room temperature. Tubulin was purified from the packed cells by a modification of the Shelanski method¹⁰ of *in vitro* polymerisation (but only one cycle) as described previously⁸. Pellets of polymerised tubulin were resuspended in 100 mM sodium *N*-morpholinoethanesulphonate (MES), pH 6.4, 1.0 mM EGTA, 0.5 mM MgCl₂, and 1.0 mM GTP, and chilled on ice for 1 h for depolymerisation. The suspensions were then centrifuged at 100,000g for 1 h at 4 °C, and the pellets discarded. Aliquots of the supernatants (purified tubulin) were added to mixtures that finally contained: 8.5 µg protein, 33 mM MES, 0.33 mM EGTA, 3.7 mM MgCl₂, 0.4 mM GTP, and 6.7 mM sodium phosphate, pH 6.8, in a volume of 150 µl; and pre-incubated for various times at 37 °C. At the end of each pre-incubation period, 5 µl of an aqueous 0.186 mM ³H-colchicine (New England Nuclear) solution (2.16 Ci mmol⁻¹) were added to the samples to be tested for binding activity, and an additional incubation was carried out for 1 h at 37 °C. Subsequently the samples were analysed using DEAE-Sephadex column chromatography¹¹. All assays were run in triplicate and the data points shown represent the average values. The curve was constructed by linear least-squares fitted to these values. The total time includes pre-incubation plus the 1 h of incubation with ³H-colchicine. Protein was determined according to the method of Lowry *et al.*¹⁵.

bulk (about 90%) of the polymers formed consisted of tubules; the rest were ribbons.

A plot of the assembly data of one experiment is shown in Fig. 2, in which the decay was measured over a period of 2 h. As with the decay of colchicine-binding activity, the loss of polymerisability followed apparent first-order kinetics. Its rate seemed to be faster, however, than that of the former by an order of magnitude. The half life was calculated to be only 25.0 ± 1.8 min. Addition of supplementary fresh GTP to the solutions did not affect the amount of polymer formed at any time. Since these data suggested that the decay of some factor other than tubulin itself might have been responsible for the rapid decay of polymerisability, we attempted to supplement C₆ tubulin preparations with microtubule-associated protein, τ factor³, which has been shown to be essential for the formation of microtubules from preparations of hog brain tubulin. The addition of such hog brain factor to polymerisation mixtures of C₆ tubulin not only increased the amount of C₆ polymers formed in general, but, most interestingly, it induced the formation of tubules even at times after the polymerisability of non-supplemented tubulin had decreased to zero. Table 1 presents data obtained from such an experiment. Note that even after a pre-incubation of 510 min (about 3 h after the polymerisation of the tubulin preparation alone became undetectably low) the amount of polymer formed in the presence of heterologous τ factor exceeded by 19-fold the quantity formed with comparatively fresh preparations (60 min pre-incubation) in the absence of added factor.

Our results strongly suggest that the polymerisability of C₆ tubulin preparations depends on the integrity of some

Fig. 2 Decay rate of polymerisability. $t_{1/2} = 25.0 \pm 1.8$ min. Preparations of depolymerised, purified tubulin were obtained as described in Fig. 1, except that the pellets of polymerised tubulin were resuspended in 25 mM MES, pH 6.4, 1.0 mM EGTA, 0.1 mM EDTA, 0.5 mM $MgCl_2$ and 1.0 mM GTP. At the time indicated, 50- μ l aliquots were incubated for 15 min at 37 °C. A standard solution of tomato bushy stunt virus (BSV) was then added and the mixture sprayed with 5% uranyl acetate, using a dual nebuliser, on to a carbon-coated collodion grid¹². The number of BSV was counted and the lengths of the microtubules and ribbons measured in three drop patterns for each data point. The percentage of the protein present as polymer was then calculated from these data, with knowledge of the final concentrations of tubulin (6.80 mg ml⁻¹) and BSV (0.495 mg ml⁻¹)¹².

endogenous factor other than tubulin itself. Alternatively, it is possible that tubulin could exist in multiple states with the polymerising capacity of a tubulin molecule decaying independently from the colchicine-binding ability and that τ factor could reverse the loss of polymerising function. But the simpler explanation, involving only loss of a factor, seems more likely. The decay of this factor must be more rapid than that of the tubulin, since the tubulin could still be polymerised at a time when the activity of this factor was already too low to induce any polymer formation. The data also demonstrate that even initially the concentration of this factor in active form is a limiting element in microtubule assembly from C₆ tubulin.

The experimental conditions used for measuring the decay of colchicine-binding activity and that of polymerisability differed from each other in several aspects, such as the protein concentrations of the assay mixtures, the temperatures of pre-incubations before the tests and the slightly different compositions of the buffer solutions. We believe, however, that the results shown in this report provide a conservative estimate of the divergence between the polymerisability and colchicine-binding decays. For

Table 1 Influence of heterologous τ factor on polymer formation

Pre-incubation time on ice (min)	τ concentration (mg ml ⁻¹)	Percentage protein as polymer
60	0	0.28
330	0	< 0.01
510	0	< 0.01
510	0.61	5.32

A fresh preparation (see Fig. 2) of depolymerised tubulin (7.5 mg ml⁻¹) was incubated at 0–4 °C. At the times indicated, aliquots were taken and incubated for 15 min at 37 °C. The extent of polymer formation (percentage total protein as polymer) was then determined by quantitative electron microscopy as described in Fig. 2. The formation of polymers in the presence of τ factor was determined after mixing tubulin and τ factor at a ratio of 2:1 (v/v) before incubation at 37 °C. The τ factor fraction was isolated by phosphocellulose chromatography⁹ from hog brain microtubule protein that had been purified by three cycles of polymerisation and depolymerisation¹⁰. After elution from the column, the preparation was dialysed against 50 mM ammonium acetate, pH 6.4, and 10 mM 2-mercaptoethanol, concentrated by vacuum dialysis against the same buffer, and then stored frozen. Each data point shown represents the average measurement of three drop patterns.

example, if we had been able to increase the protein concentration of the colchicine-binding assay mixture to the level used for measuring polymerisation, the difference between the two measured decay rates would have been even greater than it was, since the decay of colchicine-binding activity is known to slow down as tubulin concentrations are elevated¹. Similarly, the performance of pre-incubations at 0–4 °C (before colchicine-binding activity assays) instead of at 37 °C, only lengthened the half-life of the colchicine-binding activity (ref. 4 and G.W., unpublished). The modest levels of glycerol remaining in the tubulin preparations actually resulted in underestimation of the difference in decay rates; the concentration of residual glycerol was 100 times less in colchicine binding than during polymerisation.

In conclusion, we have shown that with tubulin purified from cultured C₆ glial cells, the capacity for microtubule assembly decays at a much faster rate than the tubulin molecules themselves. Presumably, the decay rate of polymerisability expresses primarily alteration or loss of endogenous protein factors that co-purify with tubulin through repeated cycles of *in vitro* polymerisation and depolymerisation.

We thank R. C. Williams for advice and the use of his laboratory; and Ms Nancy Steinhaus and Ms Carol Hensley for assistance. This work was supported by the NSF, the USPHS and the National Cancer Institute.

Translocation of intracellularly stored calcium during the contraction-relaxation cycle in guinea pig taenia coli

ALTHOUGH it has been shown that, in vertebrate smooth muscles, cation binding sites are localised in some intracellular structures^{1–7}, and that isolated microsomal fraction can accumulate Ca in the presence of ATP (refs 8–10), the role of the Ca-accumulating structures in the contraction-relaxation cycle is not firmly established. Using potassium pyroantimonate, which is known to penetrate intact cell membrane in the presence of osmium to produce an electron-opaque precipitate with intracellular cations^{11,12},

Fig. 1 *a*, Record of isometric tension during the procedure used to determine Ca localisation in the resting fibres. Spontaneous rhythmic contractions were eliminated by the addition of 1 mM procaine and 5 mM Mn ions before the application of the pyroantimonate-osmium solution (Os). *b*, Cross section of the resting fibres showing the localisation of the precipitate around the peripheral part of the fibre. N, nucleus. SR, sarcoplasmic reticulum. Unstained, scale bar 1 μ m. *c*, High-magnification view around the plasma membrane. The precipitate is mostly located inside the external lamina (EL) of the plasma membrane. ICS, intercellular space. Unstained, scale bar 0.1 μ m.

experiments on a molluscan smooth muscle have provided evidence that Ca localised in some intracellular structures is released into the myoplasm during mechanical activity^{13,14}. We have used this method to investigate the role of the intracellular Ca-accumulating structures in the contraction-relaxation cycle of guinea pig taenia coli. When guinea pig taenia coli was fixed at rest the electron-opaque precipitate containing Ca was observed at or near the plasma membrane. If the fixation was made at the peak of mechanical activity, the precipitate was diffusely distributed in the myoplasm.

Pieces of taenia coli (5–10 mm long) were mounted horizontally in an experimental chamber (3 ml) filled with oxygenated Krebs solution at 37 °C; one end of the preparation was clamped and the other end connected to a strain gauge to record isometric tension. After each experiment the preparation was fixed by replacing the experimental solution with 1% OsO₄ solution (adjusted to pH 7.4 with 0.01 M acetic acid) containing 2.5% potassium pyroantimonate (K[Sb(OH)₆]), dehydrated with ethanol, and embedded in Epon 812. Sections with gold colour were examined with a Hitachi HU-12 electron microscope.

The localisation of Ca-accumulating structures in the resting muscle fibres was examined in the following way.

The preparation was first kept in Krebs solution for more than 20 min, and immersed in isotonic KCl solution containing 2.5 mM potassium pyroantimonate for 10 min to introduce the pyroantimonate into the fibres during membrane depolarisation (it did not readily penetrate polarised resting membrane). The preparation was then returned to Krebs solution, and after 5–10 min procaine (2 mM) and Mn ions (5 mM) were added to eliminate spontaneous mechanical activity (Fig. 1*a*); the preparation was fixed with the pyroantimonate-osmium solution with no detectable tension development.

Figure 1*b* shows the cross section of the resting fibres fixed by the above method. It can be seen that particles of electron-opaque precipitate are mostly located around the peripheral part of the fibre. Examination of the plasma membrane with higher magnifications (Fig. 1*c*) indicates that a large amount of precipitate is located inside the external lamina of the plasma membrane (probably at the inner surface of the plasma membrane and at the sarcoplasmic reticulum). The precipitate was also observed at the nucleus. Similar localisation of calcium oxalate deposits has been reported in guinea pig taenia coli fixed after treatment with potassium oxalate⁴.

In other experiments the preparation was made to contract with acetylcholine (10⁻⁵ M) and fixed at the peak of resulting contracture tension (Fig. 2*a*). The fall of tension at the completion of fixation was 20–30%. As shown in Fig. 2*b*, the precipitate was diffusely distributed in the myoplasm in the form of a number of particles, while little precipitate was seen at the periphery of the fibre. The amount of precipitate at the nucleus apparently remained unchanged. Similar results were obtained in the fibres fixed at the peak of spontaneous contractions.

For chemical identification of the precipitate, the sections

Fig. 2 *a*, Record of contracture tension induced by 10⁻⁵ M acetylcholine (ACh), and its decline after 30 min in the pyroantimonate-osmium solution (Os). *b*, Cross section of the fibres fixed at the peak of the contracture tension. The precipitate is diffusely distributed in the myoplasm in the form of a number of particles, while it is hardly observable around the peripheral part of the fibre. Unstained, scale bar 1 μ m.

Fig. 3 X-ray spectrograph of the precipitate. The peak at 3,620 eV (arrow) is regarded as a combined spectrum of Sb-L α and Ca-K α lines. Thick vertical line indicates the standard peak of Sb-L α line (3,600 eV).

were analysed with an energy dispersive X-ray microanalyser (EDAX-707A) attached to a Hitachi HHS-2R electron microscope (accelerating voltage 25 kV, counting time 400 s). The X-ray spectrograph of the precipitate in both the resting and the contracted fibres showed a distinct peak at 3,620 eV (Fig. 3). Model tests with Ca and antimonate¹⁵ suggest that this spectrum results from the combination of Sb L-line (3,600 eV) with Ca K-line (3,690 eV). This indicated the presence of calcium pyroantimonate in the precipitate. Quantitative analysis of the precipitate was further made with another energy dispersive X-ray microanalyser (EDAX-707B) attached to a JEOL JEM-100C electron microscope together with a computerised EDIT system (accelerating voltage 40 kV, counting time 400 s). As shown in Table 1, the result again showed the presence of Ca in the precipitate in both the resting and the contracted fibres, though its concentration ratio was smaller than those of K and Na. The presence of Mg was not detected. But, considering that the amount of Ca ions involved in the activation of the contractile system is far smaller than those of K and Na ions in the myoplasm¹⁶, the values of concentration ratio of Ca in the precipitate may be taken to indicate that the precipitate serves as a measure of Ca localisation.

In conclusion, the translocation of the precipitate containing Ca from the peripheral intracellular structures into the myoplasm during mechanical activity seems to be consistent with the view that, in guinea pig taenia coli, the contraction-relaxation cycle is regulated by the release of Ca from, and its uptake by, the intracellular Ca-accumulating structures.

We thank Dr Suechika Suzuki and Miss Yoko Narikawa

for technical assistance, and the staff of the Electron Optics Division, JEOL Ltd. for providing facilities to use the micro-analyser with the EDIT system.

Tumour-specific transplantation antigen from SV40 transformed cells binds to DNA

MUCH work is being directed towards the characterisation of tumour-specific transplantation antigens (TSTA). AL/N strain mouse embryo cells transformed by SV40 virus (SV AL/N cells) are suitable for such studies, because (1) these cells are highly antigenic and are rejected at high dose ($>10^7$) by the immunologically competent syngeneic AL/N mouse^{1,2}, (2) TSTA is common to all SV40 virus-transformed cells tested but specific in that only SV40 transformed cells share a common TSTA³, and (3), the SV40 'early' or A gene is relatively small ($\sim 1.8 \times 10^6$ molecular weight), its mapping and the nucleotide sequences of the restriction endonuclease fragments are under intense study, and the various cellular antigens in the transformed cells—the TSTA, the tumour-specific surface antigen (TSSA) (ref. 4), and the nuclear T antigen—probably represent modifications of products of this early gene⁵⁻⁷. Using SV AL/N cells and a detergent technique⁸ for solubilisation, we demonstrated that immunisation by a partially purified soluble extract containing 100 μ g protein effectively protects mice against tumourigenic doses of SV40 transformed cells⁹. We report here that TSTA activity co-purifies with the T antigen in several steps, that TSTA can be recovered from a DNA column in a fraction which then effectively immunises at the 1- μ g level, and that the TSTA, like the T antigen¹⁰, binds to double-stranded mammalian DNA.

Nuclear preparations from an SV40 transformed human cell line are rich in TSTA activity³. Accordingly, fractions from murine SV AL/N cells enriched in nuclei and also containing the cytoplasmic membranes were sonicated and solubilised by the detergent technique. Details are given in Table 1. Antigen enrichment was by precipitation with $(\text{NH}_4)_2\text{SO}_4$ followed by DEAE-cellulose chromatography¹¹. A large amount of the T-antigen activity of the whole extract was recovered in the $(\text{NH}_4)_2\text{SO}_4$ precipitate (84%), and in a fraction which eluted at about 0.15 M NaCl from the DEAE column (40% of input; Table 1 and Fig. 1). This pooled fraction was enriched in TSTA activity: it gave significant ($\sim 75\%$) and specific protection at the 4- μ g level, and full protection at the 20- μ g level (Table 2).

The pooled DEAE fractions were then chromatographed on a DNA-cellulose column¹⁰. About 70% of the T-antigen activity was recovered in a sharp peak (pool III, Fig. 2),

Table 1 Quantitative analysis of elemental concentration ratios in the precipitate

Element	Line	Mean ratios	
		Resting fibres	Contracted fibres
Sb	L α	1.00	1.00
Ca	K α	0.19 \pm 0.07	0.12 \pm 0.05
K	K α	0.36 \pm 0.12	0.57 \pm 0.06
Na	K α	0.23 \pm 0.10	0.35 \pm 0.12

Values are means \pm s.e.m. Data for resting fibres from seven specimens, for contracted fibres from five specimens.

Table 1 Distribution and recovery of T-antigen activity

	CF units ($\times 10^3$)	Protein (mg)	Specific activity (CF units mg^{-1}) $\times 10^2$
Whole extract	310	82	37.5
0-50% $(\text{NH}_4)_2\text{SO}_4$ precipitate	255	60	42
DEAE column input	235		
pool recovery	95	12	50
DNA column input	59		
pool III recovery	42	3	140

Subconfluent SV40 transformed AL/N murine embryo cells (SV AL/N line) were grown as before², the cells were collected by scraping, and washed three times with Tris-buffered saline, pH 7.4. To the washed cells was added three times the pellet volume of ice-cold buffer containing 10 mM NaCl, 10 mM Tris-HCl, pH 7.8, 1.5 mM MgCl_2 , 1 mM dithiothreitol (DTT), 100 μM L-1-tosylamide-2-phenylethylchloromethyl ketone (TPCK) and 100 μM phenylmethylsulphonylfluoride (PMSF) (buffer I). The suspension was homogenised by four strokes on a Dounce homogeniser, and centrifuged at 700g for 10 min. The pellet, containing mainly nuclei and cytoplasmic membranes, was suspended in three times its volume of buffer I, given four strokes on a Dounce homogeniser and centrifuged again at 700g for 10 min. The pellet was resuspended in buffer II containing 0.02M Tris-HCl, pH 8.2, 0.08M NaCl, 1mM DTT, 10% glycerol, 0.001% Triton X-100, 100 μM each TPCK and PMSF¹¹. The suspension was sonicated for 1 min and centrifuged at 27,000g for 1 h. The pellet was resuspended in the same volume of buffer II, homogenised and centrifuged as before. The two supernatants were combined, designated as whole extract, and precipitated with ammonium sulphate to a final concentration of 50%. Further fractionation was achieved on a DEAE-cellulose column as in Fig. 1, followed by a DNA-cellulose column as in Fig. 2. T antigen was measured by standard microtitre complement fixation assay, and units were calculated as in ref. 6. Anti-T antiserum was provided by Dr J. Gruber (NCI). Protein was determined by the Lowry technique¹⁵. Values are in complement-fixing (CF) units.

with about threefold increase in specific activity (Table 1).

When the pooled fractions from the DNA-cellulose column were tested for TSTA, only those fractions which bound to calf thymus DNA had this activity. More than 50% protection was provided against 10-100-fold tumourigenic doses of mKSA-ASC tumour cell challenge by 1 μg , and full protection of 5 μg , of pool III material. Pooled fractions I and II, which did not bind to DNA and had no T antigen activity, were found to be inactive in the TSTA test at 40-60- μg level. The pooled fraction IV, which bound to the DNA column, had significant TSTA activity at the 10- μg level (Table 2).

It is significant that the T antigen and TSTA from SV40 transformed AL/N cells co-purify through ammonium

Fig. 1 Elution of T antigen from DEAE-cellulose column. The 0-50% ammonium sulphate precipitate (see legend to Table 1) was dialysed against buffer III containing 0.05M Tris-HCl pH 7.8, 1 mM DTT, 100 μM each TPCK and PMSF, and 10% glycerol. The dialysed material was chromatographed on a DEAE-cellulose (DE-52, Whatman) column ($8 \times 2 \text{ cm}$), eluted by a gradient of 0-0.4M NaCl in buffer III, as reported previously¹¹. The CF titre recovered is the reciprocal of the dilution of a 25- μl aliquot which fixes 50% of the complement⁶. The peak of T-antigen activity eluted at 0.15 M NaCl, as observed before^{11,16}. The fractions designated by the horizontal bar were pooled, and used for the DNA column fractionation (Fig. 2).

Fig. 2 Elution of T antigen from DNA-cellulose column. The pooled fractions from the DEAE-cellulose column (Fig. 1), were dialysed against 5 mM potassium phosphate buffer, pH 6.2, containing 0.1 M NaCl, 1mM DTT, 100 μM each TPCK and PMSF, and 10% glycerol. A double-stranded DNA-cellulose column ($12 \times 1 \text{ cm}$) was made from Sigma calf thymus DNA as before¹⁰. The potassium phosphate buffer was replaced, when fraction number 22 eluted, with buffer IV containing 10 mM Tris-HCl, pH 8.0, 0.6 M NaCl, 1 mM DTT, 100 μM each TPCK and PMSF, and 10% glycerol, to elute T-antigen activity¹⁰. Fractions were analysed for Δ , T antigen (CF) and \bullet , absorbance (280 nm), and pooled as defined by the horizontal bars, for TSTA determination (see Table 2).

sulphate precipitation, DEAE- and DNA-cellulose column chromatography, and that both T and TSTA specific activities were enriched through the binding to the DNA.

By studying temperature sensitive SV40 mutant viruses defective in the early A region (the tsA mutants)¹², it was found that the expression of T and TSTA is modulated coordinately^{6,13,14}. Adeno-SV40 hybrid viruses with SV40 T and/or TSTA antigen activity induce proteins with apparently overlapping regions in their polypeptide

Table 2 TSTA activity

Immunisation with	Dosage (μg protein)	Tumour cells for challenge	Tumours/total inoculated	P values

Adult BALB/c mice were injected intraperitoneally (i.p.) twice with the indicated dose of protein at a 1-week interval. Ten days after the second injection the mice were challenged i.p. with the indicated number of the SV40 transformed BALB/c mKSA-ASC cells^{17,18} (provided by Dr L. W. Law), or intramuscularly with the methylcholanthrene transformed Meth-I-A BALB/c cells which carry their own TSTA¹⁹, for specificity control²⁰. The TD_{50} of the mKSA-ASC cell¹⁸ is 10^2 - 10^3 , the TD_{50} of the Meth-I-A is about 10^4 cells. Evidence of ascites tumour appeared by about 2 weeks in control mice, with a mean time to death of 20 d after challenge. Inoculated mice were followed for 5 weeks. The differences in the P values²¹ between immunised and non-immunised groups are significant where given.

sequences⁷. Nuclear fractions from SV40 transformed human cells are enriched in T antigen and also in TSTA⁸.

Our findings give independent confirmation of the suggested homology between T antigen and TSTA, two of the biologically important products of the early SV40 gene in SV40 transformation. Furthermore, the binding of TSTA to double-stranded mammalian DNA opens the possibility of molecular study of the paradoxical dual role of this protein: first as a tumour rejection antigen *in vivo*, and second as a candidate regulatory protein for the growth of cells in tissue culture.

Productive T7 infection of *Escherichia coli* F⁺ cells and anucleate minicells

THE development of colivirus T7 is largely independent of host cell functions and dependent on T7-encoded enzymes, for example, T7 RNA polymerase, DNA replication enzymes, and lysozyme^{1,2}. In view of this relative independence, the failure to propagate in *Escherichia coli* cells carrying an F factor^{3,4} or in anucleate minicells⁵ is particularly interesting with respect to a molecular understanding of host-virus interaction. We report here that T7 can, at a low frequency, productively infect both F⁺ cells and minicells derived from either an F⁺ or an F⁻ *E. coli* culture. The percentage of T7 permissive cells within an F⁺ population is dependent on the growth conditions of the culture but does not seem to be directly related to a specific phase of the cell cycle.

T7 produces approximately 10,000 times more plaques when plated on an F⁻ lawn of *E. coli* cells compared with F⁺ lawns. The plaques produced on an F⁺ lawn are irregular in size and do not contain selected mutant or host-cell-modified phage, as phages isolated from these plaques have no increased ability to grow on lawns of F⁺ cells. All attempts to isolate mutants of T7 capable of plating on F⁺ and F⁻ cells at the same efficiency, have so far failed. Although previous results suggest a role for a T7 early product in the exclusion of T7 by F⁺ cells⁶, we have observed exclusion of T7 deletion mutants lacking all early functions. Thus, it seems likely that the 'non-permissiveness' cannot be overcome by mutations in T7. This led us to examine factors related to the F⁺ *E. coli* cell which determine the 'non-permissiveness'.

After quantitation, we found that 2-50% of an F⁺ cell population could propagate T7, depending on growth conditions (Fig. 1a). F⁺ cells were grown in various media, infected with T7, and the infected cells plated with F⁻ indicator bacteria. A culture grown in rich medium contained the highest number of T7 permissive cells. Culture conditions therefore influence strongly the fate of T7 in F⁺ cells, by altering the ratio of permissive and non-permissive cells. The permissive F⁺ cells release a burst of T7 comparable in size with that released from F⁻ cells (Fig. 1b), indicating that once an F⁺ cell is committed to permissiveness the subsequent T7 development is normal.

In the same F⁺ cell culture, there seem to be two types of cells. This heterogeneity could not result from segregation of the F factor as identical results were obtained when growth was dependent on the presence of the F factor. As explanations for the heterogeneity we will consider the following possibilities: (1) productive infection occurs in cells which lose the plasmid during infection, for example, infection of cells in the process of cell division; (2) the permissive cells retain the plasmid but pass through a T7 permissive phase during the cell cycle; (3) each cell at any stage of the cell cycle can be infected either productively or abortively, depending on a statistical event during the infection process.

The observation that the growth rate of a culture of F⁺ cells altered the percentage of T7 permissive cells, suggested that the heterogeneity within the population for T7 permissiveness may reflect a stage within the *E. coli* life cycle. We have attempted to demonstrate an increase in the number of productively infected cells at some stage in the cell cycle by infecting *E. coli* F⁺ cells synchronised by a variety of techniques (that is, thymine and amino acid starvation,

Fig. 1 Detection of T7 permissive F⁺ cells. *a*, *E. coli* 803 F⁻ and 803 F⁺ (ref. 6) were grown in various media and, at a cell density of 5×10^8 ml⁻¹, infected with T7 am 193⁺K⁺ (ref. 6) at a multiplicity of infection of 10 (30 °C). After 5 min, T7 antiserum was added and allowed to act for 3 min. Then the p.f.u.s were determined by plating aliquots with *E. coli* 803 F⁻ indicator bacteria. The p.f.u.s indicate T7 permissive cells. The p.f.u.s obtained with 803 F⁺ were plotted as a percentage of the total cell count against generation time of the bacteria. Total cell count was equal to the number of p.f.u. obtained in the F⁻ culture. Generation time varied with the culture conditions: tryptone-yeast broth, 40 min; M9 0.4% glucose supplemented with casamino acids, thymine, and thiamine¹¹, 50 min; M9 0.4% glucose supplemented with 0.03% casamino acids, 75-85 min; M9 0.4% glucose, 130 min and M9 0.4% succinate, 170 min. *b*, One-step growth curves of T7 development in *E. coli* F⁻ and F⁺. As in *a*, 803 F⁻ and F⁺ were grown in tryptone-yeast medium and infected, at a density of 5×10^8 ml⁻¹, with T7 am 193⁺K⁺. After 5 min, T7 antiserum was added and, at 8 min, the culture was diluted $1:10^4$ to dilute out the antibodies. p.f.u.s were determined at various times thereafter, by plating on 803 F⁻ bacteria.

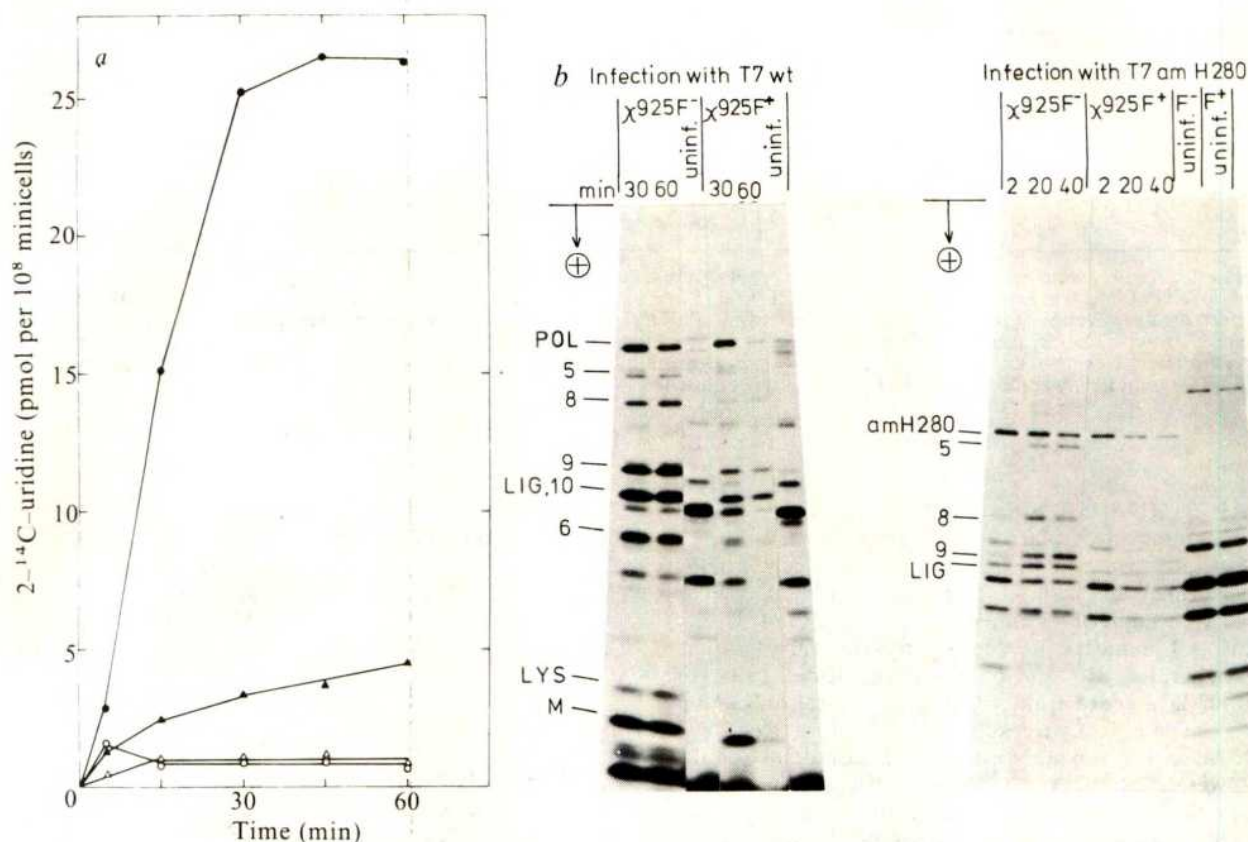

Fig. 2 T7 gene expression in anucleate minicells derived from F⁻ and F⁺ strains. The minicell producing strain χ925 (ref. 15) and an isogenic F⁺ derivative were grown in L broth to $A_{600} = 0.8$. Minicells (2×10^8 ml⁻¹) were infected with T7 at 0 °C in M9 glucose minimal medium containing 10 μg ml⁻¹ threonine and 10 μg ml⁻¹ leucine (multiplicity of infection = 20). 2-¹⁴C-uridine (0.11 μCi ml⁻¹, 59 mCi mmol⁻¹) was added and the suspensions were placed at 30 °C. Samples (100 μl) were taken at various times, mixed with 100 μl lysozyme solution (2 mg lysozyme per ml TES, that is, 0.05 M Tris-HCl, pH 7.6, 0.1 M NaCl, 0.05 M EDTA) and rapidly frozen by immersion of the tubes in liquid nitrogen. When all samples had been taken they were simultaneously placed at 37 °C for 2 min; 20 μl of 2% sarkosyl in TES was added followed by 2 ml ice-cold 5% TCA. Cold TCA-precipitable material in each sample was measured as described previously¹⁵. ●, F⁻ minicells, infected; ○, uninfected; ▲, F⁺ minicells, infected; △, uninfected. **b**, Protein synthesis. Minicells were resuspended in M9 glucose minimal medium containing 10 μg ml⁻¹ threonine and 10 μg ml⁻¹ leucine and were infected with either T7 am 193⁺K⁺ or T7 am H280 (T7 RNA polymerase⁻, protein kinase⁻) at a multiplicity of infection of 10. At various times (as indicated), ¹⁴C-amino acids were added (25 μCi ml⁻¹). After a further 20 min of incubation, the infected minicells were removed from the radioactive medium by centrifugation, and dissolved in sample buffer for polyacrylamide gel electrophoresis. Autoradiograms of 10–20% gradient gels are shown. This figure, in addition to the information discussed in the text, covers two aspects. (1) The expression of stable mRNA in minicells¹⁸ can be detected. After infection with T7, the expression of this mRNA is stopped, indicating translational control¹⁹. (2) A comparison between products made from stable mRNA in the minicells derived from F⁻ and F⁺ cells, reveals one major difference. One additional peptide of molecular weight of about 25,000 is synthesised in the F⁺ minicells. Thus, the sex factor also seems to code for an extremely stable messenger.

use of *dna*⁻ts mutants, successive fractionation of progeny cells, and fractionation of cells according to size). We have so far been unable to demonstrate any relationship between the division cycle of *E. coli* and productive T7 infection. The possibility still exists that the techniques used for synchronising cell division, did not synchronise the event responsible for T7 permissiveness (for example, the state of F factor replication). Although negative, these results argue against our first two suggestions for T7 permissiveness of F⁺ cells.

Inhomogeneity in each cell may be mediated by the cell envelope. Inhomogeneities of the cellular surface with respect to newly synthesised areas have, for example, been found using phage receptors as probes^{7,8}. The role of the membrane in the abortive infection of F⁺ cells by T7 has indeed been documented^{6,9–11}, and we know from earlier experiments that no soluble factor can be responsible for the exclusion⁶. We hypothesise, therefore, that the membrane carries 'permissive' and 'non-permissive' entry sites for T7. Depending on the growth conditions, the episome influences the ratio of the two sites. From this hypothesis we expect that after loss of the episomal DNA, cells would regain up to 100% T7 permissiveness, dependent on growth of the cell envelope, but would retain the ability to exclude

T7 if no growth occurred. These two conditions were tested using *E. coli* carrying the temperature-sensitive *F*_{L101} lac episome and using minicells derived from F⁺ parent cells.

After shift of an *E. coli* *F*_{L101} lac culture from 30 °C to 42 °C, F replication stops and the F DNA is diluted out with cell division. The re-appearance of T7 permissiveness followed the segregation kinetics with a brief lag period (not shown). These data would be consistent with the assumption of a continuous regeneration of permissive membrane sites.

Conditions in which the cellular surface is not significantly altered after loss of DNA, are found with anucleate minicells. We therefore constructed isogenic F⁺ and F⁻ strains of an *E. coli* mutant which produces anucleate minicells. The minicells formed do not contain chromosomal or episomal DNA. After infection of minicells from the F⁻ strain, uridine was rapidly polymerised into a TCA-precipitable form (RNA), whereas the infected F⁺ minicells synthesised very much less RNA (Fig. 2a). The uninfected F⁺ and F⁻ minicells did not produce significant amounts of TCA-precipitable material. This difference in the patterns of RNA synthesis is very reminiscent of the difference observed in nucleated cells^{8,12}. The initial rate of synthesis is similar between F⁻ and F⁺ nucleated cells whereas at later times the

Table 1 T7 development and recombination in *E. coli* minicells

Expt	Minicells (ml ⁻¹)	Mating type of parental cells	Plaque-forming units (p.f.u.) ml ⁻¹ resulting from infection of minicells by:				p.f.u. resulting from minicells coincidentally infected by T7 mutants and subsequently mixed		Viable cell count (ml ⁻¹)
			T7 ⁺	T7 gene 11 ⁻	T7 gene 17 ⁻	T7 gene 1 ⁻	by pairs of T7 mutants	singly infected T7 mutants	
1	2 × 10 ¹⁰	F ⁻	8 × 10 ⁷	< 10 ³	2 × 10 ⁴	—	3.3 × 10 ⁶	1.8 × 10 ⁴	1 × 10 ²
2	1 × 10 ⁹	F ⁻	4 × 10 ⁶	< 10 ³	—	< 10 ³	2 × 10 ⁴	—	1 × 10 ³
	1 × 10 ⁹	F ⁺	5 × 10 ⁶	< 10 ³	—	< 10 ³	3 × 10 ³	—	1 × 10 ³

Before infection, minicells were (expt 1) or were not (expt 2) pre-incubated in L broth containing 20 µg cycloserine ml⁻¹, at 37 °C for 1 h. The multiplicity of infection was 10 (expt 1) or 5 (expt 2). After 5 min at 37 °C, T7 antiserum was added. At 7 min, the infective centres (p.f.u.) were determined by plating with B₁ (B strain, *su*⁻) as indicator bacteria. The following viral mutants were used²⁰: T7 am 37 (gene 11⁻); T7 am 145 (gene 17⁻) and T7 am 27 (gene 1⁻). To confirm that recombination had occurred within the minicells, we mixed singly infected minicells after the antiserum treatment and plated for infective centres after additional 5 min of incubation. A 50-fold increase in the parental cell count (by addition) did not change the number of infective centres obtained.

synthesis of RNA in the F⁺ cell terminates because of the general shut-down of macromolecular syntheses^{8,12}.

An unequivocal comparison of specific viral gene products was performed at the level of protein synthesis. Whereas infected F⁻ minicells synthesised all early and late T7 proteins, F⁺ minicells produced only the early proteins, again in parallel with the process in nucleated cells (Fig. 2b). Both late genes transcribed by the viral RNA polymerase and late genes transcribed by the host RNA polymerase (as in the polymerase-protein kinase double mutant H280), were affected. At later times, early protein synthesis in F⁺ minicells was also decreased as in whole cells. From these experiments we conclude that minicells are efficiently infected with T7 and that they produce T7 products in the same order of magnitude as do nucleated cells. This provided evidence for the existence of sufficient host cell RNA polymerase in the minicells to permit transcription of infecting phage genomes as has been described previously for phage infection of minicells produced by *Bacillus subtilis*¹³. The time course of synthesis is, however, expanded by a factor of 5–10 (Fig. 2b). Thus, in minicells a factor must be rate-limiting which is not limiting in nucleated cells. In addition, infection of minicells with T7 carrying a known amber mutation led to the loss of the affected protein and production of the corresponding amber fragment (Fig. 2b), indicating that recognition of nonsense codons occurs normally in minicells.

To determine whether the F⁺ minicells were heterogeneous and contained a fraction of permissive cells, we examined the development of virus particles in F⁻ and F⁺ minicells. Although only little DNA replication was detectable by thymidine incorporation (not shown), a low but significant and reproducible number of F⁻ minicells released virus particles (0.1%). Among the infected F⁺ minicells (grown in rich medium), a fraction of about 0.01% propagated T7. This is similar to the situation in nucleated cells in which a fraction of the cells is also T7 permissive (Fig. 1a and b).

We were unable to demonstrate a one step growth curve with minicells and would suggest that this is due to a very asynchronous release of a small number of progeny phage. Because of the inherent problems in demonstrating that only one out of 1,000 or 10,000 infected minicells produced phage, the results were confirmed by recombination experiments (Table 1). A significant number of recombinant virus was detected after doubly infecting F⁻ and F⁺ minicells with T7 amber mutants.

In conclusion, we believe that the results reported here indicate that T7 development in F⁺ cells is abortive or permissive, dependent on the growth conditions of the *E. coli* cell culture. The decision as to successful or abortive infection is made at the time of infection and contained within the existing structure of the cell as minicells which

do not contain genetic information show the same properties as do whole cells.

Ratios of α -to β -globin mRNA and regulation of globin synthesis in reticulocytes

THE genomes of several mammalian species contain at least two α globin loci and a single β globin locus so that the ratio of α - to β -globin genes is 2 : 1 or more^{1–3}. Despite this difference in number of genes, reticulocytes from these species synthesise equal numbers of α - and β -globin chains indicating that compensatory regulation must occur. Cytoplasmic mRNA is an intermediate between the gene and globin protein, and it has been suggested that the cellular α/β mRNA ratio is an important factor in achieving balanced globin synthesis^{4–6}. We report here an excess of 30% α mRNA on reticulocyte polysomes of rabbits, mice, and sheep. Our data also illustrate the potential for errors in studies in which only poly(A)⁺ RNA is assayed.

Using inhibitors of polypeptide elongation in rabbit reticulocytes, Lodish has demonstrated that β mRNA initiates polypeptide synthesis 40% faster than α mRNA; and since the rate of elongation of the two globin polypeptides is equal, he inferred that a 40% excess of α mRNA on polysomes is required to achieve balanced globin

synthesis⁵. Others have inferred a functional α/β RNA ratio of 1.3:1.8 in rabbits⁶.

Attempts to measure directly the molar ratio of α to β mRNA in reticulocytes have led to conflicting results. Formamide gel electrophoresis of poly(A)⁺ RNA obtained by oligo(dT)-cellulose chromatography has yielded α to β mRNA ratios as low as 1 and as high as 1.6 (refs 7-12). Recently single determinations using hybridisation with cDNA probes of 85% specificity have given α/β RNA ratios of 1.1 and 1.5 in total RNA of mouse and poly(A)⁺ RNA of human reticulocytes^{12,13}.

Globin mRNAs of rabbit, mouse and sheep were separated by formamide gel electrophoresis⁷⁻¹². Although these mRNA templates seemed 80-90% pure by gel analysis after a single electrophoretic step, cDNAs made from these templates were 20-40% cross-contaminated by hybridisation analysis. This cross-contamination is presumably due to incomplete separation of the two mRNAs caused by heterogeneity in the poly(A) content of each. To improve mRNA separation, and thus the specificity of the cDNAs, we subjected each globin mRNA to two electrophoretic procedures (Fig. 1). The α and β cDNAs made from these purified templates were then hybridised to increasing concentrations of mRNAs (Fig. 2). The percentage specificity of a cDNA was calculated by subtracting from 1 the ratio of the amount of homologous to heterologous mRNA needed to half-saturate that probe and multiplying the answer by 100 (refs 12, 13). Heterologous and homologous

Fig. 1 Separation of α and β globin mRNAs by polyacrylamide gel electrophoresis in formamide. Total cellular RNA and polyosomal RNA of reticulocytes were isolated^{21,22} and separated into poly(A)⁺ and poly(A)⁻ fractions by oligo(dT)-cellulose chromatography²³. Poly(A)⁻ fractions were chromatographed three or four times to remove traces of poly(A)⁺ RNA. Poly(A)⁺ RNA was subjected to electrophoresis on 5% polyacrylamide cylindrical gels in 98% formamide-20 mM Na barbital and 20 mM NaCl at 3.5 mA per gel at 24 °C for 2-3 h¹². Globin mRNAs were located by scanning unstained gels at 260 nm and gel pieces containing the α and β mRNAs were excised and incorporated with the same polarity into separate 7% polyacrylamide gels. After a second electrophoresis at 3.5 mA per gel for 3-4.5 h at 24 °C, the mRNAs were again located by ultraviolet scanning and the pertinent gel fractions were excised. In some experiments, RNA was eluted electrophoretically into dialysis bags⁷. The eluate was extracted with phenol, centrifuged to remove gel particles, re-extracted twice with chloroform and made 70% in ethanol to precipitate the mRNA. In recent experiments a different procedure which resulted in a twofold increase in yield was used. The gel pieces were driven through a 25-gauge needle with 2-3 volumes of 7 M urea, 0.35 M NaCl, 10 mM Tris-HCl (pH 8.0), 1 mM EDTA, and 2% SDS. The resulting suspension was agitated at 45 °C for 2 h, underlayered with 60% glycerol, and centrifuged to remove gel pieces. After the aqueous layer was extracted twice with phenol and twice with chloroform, the RNA was precipitated with ethanol and purified by oligo(dT)-cellulose chromatography. (J. Ross, personal communication). *a*, Poly(A)⁺ RNA of C57 B1/6J mouse reticulocytes. After the 5% gel electrophoresis (left), each mRNA was excised and rerun in a 7% gel (right). mRNAs were excised as indicated by the vertical lines. *b*, Reticulocyte poly(A)⁺ RNA of sheep homozygous for β^H globin after 5% gel electrophoresis.

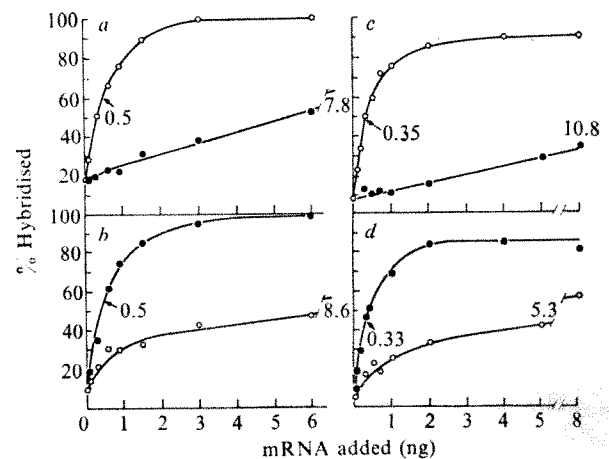

Fig. 2 Hybridisation of α and β ³H cDNAs with purified α and β mRNA templates. ³H-cDNAs were synthesised as reported²⁴ except the 100- μ l reaction mixture contained 100 μ g ml⁻¹ actinomycin D, 400 μ M each of dATP, dTTP, dCTP, and 100 μ M ³H-dGTP (10 Ci mmol⁻¹); 1-2 μ g RNA template, 0.125 μ g oligo(dT) per μ g mRNA, and 300 units per ml AMV reverse transcriptase (from NCI). After incubation at 37 °C for 1 h, 50 μ g tRNA was added, the mixture extracted with phenol, and cDNA was precipitated with ethanol. α and β cDNAs were treated for 24 h at 37 °C in 0.3 ml of 0.3 M NaOH, neutralised with 0.5 M HCl, applied to hydroxylapatite in 0.05 M Na phosphate buffer (pH 6.8) at 60 °C, and eluted in 0.14 M Na phosphate buffer (pH 6.8). The cDNAs (5-10S) were further purified by centrifugation in 10%-30% sucrose gradients (0.1 M NaCl; 10 mM Tris-HCl, pH 7.4; 1 mM EDTA; 0.5% sodium dodecyl sulphate (SDS)) at 94,000g and 24 °C for 20 h and then precipitated with ethanol. Hybridisations of ³H-cDNA to RNA were performed in sealed siliconised capillary tubes using a buffer containing 0.3 M NaCl, 30 mM Tris-HCl (pH 7), 2 mM EDTA, 0.1% SDS, and 40 μ g per ml *Escherichia coli* tRNA. Varying amounts of sample RNA and a constant amount of cDNA (500 c.p.m.) were diluted to 18 μ l, heated to 100 °C for 90 s, and then incubated 16-18 h at 68-70 °C. One-half of each sample was digested with S₁ nuclease, and the other half was an undigested control²⁵. Both samples were then precipitated with 7.5% trichloroacetic acid on to S&S nitrocellulose filters. The filters were dissolved with 0.5 M HCl at 100 °C followed by ethyl acetate at 24 °C, and Hydromix was added before counting. Half of the difference in hybridisation between zero and saturating RNA inputs is defined as half-hybridisation. Specificity was calculated as described in the text. *a*, Rabbit α cDNA = 94%; *b*, rabbit β cDNA = 94%; *c*, mouse α cDNA = 97%; *d*, mouse β cDNA = 94%; \circ , α mRNA; \bullet , β mRNA.

hybrids had identical thermal elution profiles ($\pm 1^\circ$) indicating little or no mismatching of sequence and suggesting that heterologous hybrids are due to residual contamination rather than cross-hybridisation¹². Alternatively, calculation of cDNA specificity by analysis of the shapes of curves seen in heterologous hybridisations suggests that residual contamination of the β cDNA (Fig. 2*b, d*) may be as high as 15-20%, while that of α cDNA (Fig. 2*a, c*) is near 0. But, since the contamination of β mRNA with α mRNA in Fig. 2*a* and *c* is no greater than 6% and 3%, respectively, this method of estimation may be invalid.

We have used the appropriate cDNA probes to measure the α/β RNA ratios in reticulocytes of rabbits, mice, and sheep. Typical hybridisation results are shown in Fig. 3, and the data are summarised in Table 1. In our experiments we have attempted to avoid several potential pitfalls. First, our cDNA probes, while up to 97% specific, have residual contamination. The presence of such contamination becomes more critical as one measures smaller differences in α/β mRNA ratio. Several assays using probes varying in specificity from 83% to 97% have yielded similar α/β RNA ratios in rabbit and mouse reticulocytes (Table 1). Furthermore, reconstruction experiments in

Table 1 Ratios of α -to β -globin RNA in total and polysomal RNA of rabbit, mouse and sheep erythrocytes

cDNAs	Expt no.	Minimum* specificity (%)		Total cellular RNA	α/β RNA† Polysomal RNA

Ratios were calculated from half-saturation values using α and β cDNA probes of indicated specificity. Each experiment contains data obtained with a different pair of cDNA probes and mRNA templates.

*See text for method of calculation.

†For method of calculation of α/β RNA ratios, see legend for Fig. 3.

which varying template mixtures were used demonstrated that differences in α/β mRNA ratios of 10% or more could be detected. Second, to measure molar RNA ratios while controlling for known mRNA and potential cDNA size differences, we have determined hybridisation ratios with template standards. These ratios (between 0.9 and 1.1) were used to correct observed hybridisation ratios in test samples.

In rabbit reticulocytes, molar ratios of α to β mRNA average 1.3 in total and polysomal RNA (Table 1). Similar α/β polysomal RNA ratios were obtained using three different sets of cDNA probes with specificities ranging from 83% to 94%. While the ratios of α/β mRNA in total and polysomal RNA were equal, the α and β mRNA concentrations (calculated by comparing template and sample RNA amounts needed for half-hybridisation) were greater in polysomal ($\alpha, \beta = 1.5\%, 1.2\%$) than in total RNA ($\alpha, \beta = 1.1\%, 0.8\%$) because of the presence of 4S RNA in total RNA samples. When polysomal RNA was fractionated by oligo(dT)-cellulose chromatography, both poly(A)⁺ and poly(A)⁻ fractions (see legend to Fig. 1) had the same α/β ratio, and 95% of each mRNA was in the poly(A)⁺ fraction. By subtraction of the α and β globin mRNA amounts in polysomal RNA from those in total RNA, we calculate that 9% of α mRNA and less than 1% of β mRNA are present in non-polysomal RNA of rabbit reticulocytes, in agreement with previous estimates¹⁴.

In C57 B1/6J mice, both the total and polysomal RNA of reticulocytes have average α/β RNA ratios of approximately 1.3 (Table 1, Fig. 3c and d). Again, globin mRNA concentrations are higher in polysomal ($\alpha, \beta = 1.6\%, 1.3\%$) than in total RNA ($\alpha, \beta = 1.2\%, 0.9\%$). Note, however, that poly(A)⁺ and poly(A)⁻ fractions of mouse polysomal RNA have different α/β RNA ratios (1.26 and 0.87, respectively). Also, the α/β RNA ratio in polysomal RNA calculated from the poly(A)⁺ and the poly(A)⁻ data agrees closely with the observed ratio (1.20 compared with 1.24). Since the ratio of α/β in the poly(A)⁺ RNA is 45% greater than in the poly(A)⁻ fraction, α mRNA may contain greater average poly(A) length than β mRNA in these mouse samples. Mouse and human mixed globin mRNAs are known to have different size classes of poly(A)¹⁵⁻¹⁷. The existence of different α/β RNA ratios in poly(A)⁺ and poly(A)⁻ fractions of mouse polysomal RNA suggests that such poly(A) size classes may have different distributions in α and β mRNAs. Measurement of poly(A) length in the poly(A)⁺ and poly(A)⁻ fractions should verify these differences.

Results obtained from reticulocyte RNA of homozygous β^B sheep contrast with the rabbit and mouse results. First, while the α/β ratio in reticulocyte polysomal RNA of sheep is similar to that of rabbit and mouse, about 1.4, the α/β

RNA ratio in total RNA is only 0.9 (Table 1, Fig. 3a, b). In addition, α and β mRNAs make up 1.8% and 1.5% of polysomal RNA, but only 0.62% and 0.70% of total RNA, respectively. Second, the results obtained by assays of poly(A)⁺ RNA differ greatly from those obtained for unfractionated polysomal RNA. By gel electrophoresis, the α/β RNA ratio of sheep poly(A)⁺ RNA is about 0.5, or half that of rabbit and mouse poly(A)⁺ RNA, implying an excess of β mRNA in poly(A)⁺ RNA of sheep (Fig. 1b). By hybridisation analysis, an excess of β RNA was found in polysomal poly(A)⁺ RNA ($\alpha/\beta = 0.86$), while an excess of α RNA was present in polysomal poly(A)⁻ RNA ($\alpha/\beta = 1.37$). But, the ratio of α/β RNA in polysomal RNA calculated from the poly(A)⁺ and poly(A)⁻ data does not agree well with the observed polysomal α/β ratio (1.0 compared with 1.29), possibly due to the lower specificities of the sheep cDNA probes. It is unlikely that the observed β mRNA excess in poly(A)⁺ polysomal RNA of these β^B sheep is β^c mRNA, since Benz has demonstrated with β^c specific cDNA that β^B homozygotes essentially lack β^c genes¹⁸. The proportions of sheep mRNAs in polysomal poly(A)⁻ RNA were greater than those observed in rabbit or mouse reticulocytes, but the percentages varied depend-

Fig. 3 Hybridisation of reticulocyte total and polysomal RNA to α (●) and β (○) cDNAs of sheep (a, b) and mouse (c, d). Relative concentrations of α and β mRNA are determined by comparing amounts of sample RNA needed to half-saturate each cDNA probe. Using homologous templates as reference standards, the amounts needed to half-saturate each set of α and β cDNAs usually differed by less than 10% ($\alpha, \beta = 0.27, 0.28$ and $0.35, 0.33$ ng, respectively, for sheep and mouse cDNAs shown). The ratios obtained using template standards were used to correct observed sample ratios. For example in c, $a/\beta = (17.5/15) \times (0.35/0.33) = 1.24$.

ing on whether the observed concentration of globin mRNAs in total polysomal RNA or the calculated concentration (sum of poly(A)⁺ and poly(A)⁻ RNA fractions) was used (poly(A)⁺ α = 41.25%, β = 13.17%). These results suggest a substantial difference in the α/β RNA ratio between the poly(A)⁺ and poly(A)⁻ fractions in these sheep samples.

Since poly(A) length may affect mRNA stability and/or transport from nucleus to cytoplasm, differential adenylation of globin mRNAs could be important in balancing globin chain synthesis^{19,20}. Thus, if sheep α mRNA has a shorter average poly(A) length than β mRNA, as suggested by our data, any pool of α mRNA not associated with ribosomes in early erythroid cells could be degraded at a faster rate than β mRNA, thereby accounting for the low α/β ratio observed in total RNA of sheep reticulocytes (Table 1, Fig. 3a).

Thus, our data indicate that α/β mRNA ratios in poly(A)⁺ RNA may not reflect the actual α/β ratio in unfractionated total or polysomal RNA. In this regard we have recently re-examined the accumulation of globin mRNAs in erythropoietic mouse spleen cells. Gel analyses of globin mRNAs in poly(A)⁺ total RNA of spleen had yielded α/β ratios of 0.55–0.8 at different times after phenylhydrazine injection⁹. By hybridisation, we now find a constant α/β RNA ratio of 1.25 in unfractionated total RNA at all times. In contrast, poly(A)⁺ total RNA of spleen cells have α/β RNA ratios by hybridisation which parallel those obtained previously by gel analysis (J. A. P., in preparation). Thus, while a changing α/β ratio and β excess in poly(A)⁺-selected RNA is seen with both methods, in total spleen RNA an α RNA excess is observed using specific cDNA probes.

In addition, by hybridisation we have found α/β RNA ratios in polysomes of 1.2–1.4 in rabbit, mouse and sheep reticulocytes in agreement with theoretical predictions of functional α/β mRNA ratios^{4,5}. Our results suggest that balanced synthesis of α and β chains in these species depends on an excess of α mRNA on polysomes, regardless of the relative poly(A) length of the two messages. In these animals, the α/β mRNA ratios of 1.2 to 1.4 differ significantly from the α/β gene ratios. Thus, a further regulation of gene expression presumably occurs at transcription and/or mRNA processing.

Evidence for alkali-sensitive linkers in DNA of African green monkey kidney cells

MITOCHONDRIAL DNA possesses ribonucleotide linkers^{1–3} and although double-stranded eukaryotic chromosomal DNA seems to be continuous throughout the length of the chromosome⁴ it is possible that single-stranded DNA possesses physical (nicks) or chemical (non-deoxynucleotide linkers) discontinuities. To distinguish between an *in vivo* nick and a nick introduced by shear forces during DNA extraction is very difficult with the presently available techniques. The detection of non-deoxynucleotide linkers is, however feasible, providing that denatured DNA can be sedimented in a chemical environment in which the linker is not destroyed. In these conditions, the comparison between sedimentation profiles of DNA, previously treated or not with a reagent that attacks the linker, may reveal the discontinuity. An obvious such reagent is a strong base, thus precluding the use of alkaline gradients in these experiments, and so we have attempted to use sucrose gradients in non-aqueous formamide. In addition, the

Fig. 1 Alkali-sensitive sites in green monkey kidney cell DNA. The cells were grown in glass Petri dishes, in Dulbecco's modified medium containing 10% calf serum, in a 5% CO₂ humidified atmosphere at 37 °C, and labelled for 8 h with ³H-thymidine (2 µCi ml⁻¹). The cells were washed with saline-EDTA (100 mM NaCl, 10 mM EDTA, pH 8.0) and incubated with 2.0 ml of 0.5% Triton X-100 in saline EDTA for 1 min. The nuclei remained attached to the bottom of the plate and were lysed by incubating for 30 min at 37 °C with 0.75% Sarkosyl, 1 M NaCl, 10 mM EDTA, pH 8.0. The proteins were extracted by mixing the lysate gently with equal volume of 80% phenol at 4 °C. The aqueous phase was separated by centrifugation and gently mixed again with equal volume of chloroform-isoamyl alcohol (20:5, v/v). The final aqueous phase was dialysed overnight against 2 l of 10 mM Tris-HCl, pH 7.5. Aliquots (0.25 ml) of DNA were layered on the top of 4.0-ml gradients which were 0–15% sucrose (w/v) in formamide. Centrifugation was at 32,000 r.p.m. at 30 °C in an SW-50.1 rotor (Spinco) for 4 h. A total of 26–27 equal volume fractions were dripped on to strips of Whatman No. 17 paper and radioactivity was measured as described elsewhere¹⁴. **a**, Percentage ³H-DNA from monkey cells; **b**, percentage ³H-DNA from T4 phage; ○, 100 µl of DNA solution were mixed with 50 µl of 1 M Tris-HCl, pH 7.0 and 100 µl of 0.225 M NaCl, before layering on the gradients; ●, 100 µl of the DNA solution were mixed with 50 µl of 0.45 M NaOH, incubated for 10 min at 20 °C, mixed with 50 µl of 1 M Tris-HCl followed by 50 µl of 0.45 M HCl, and then layered on the gradients. The number average molecular weights (M_n) were calculated as described elsewhere¹⁴, except that in Studier's expression the exponent 0.400 was replaced by 0.312 which was better fitted to our conditions, as determined with T4 and λ DNA. **a**, M_n (○) = 68.2; M_n (●) = 45.6; **b**, M_n (○) = 46.2; M_n (●) = 49.8.

DNA had to be extracted by a very gentle method in order to keep its average molecular weight in the range of $50\text{--}80 \times 10^6$. Using these conditions, we were able to detect alkali-sensitive linkers in chromosomal DNA of green monkey kidney cells.

A typical result is shown in Fig. 1a. DNA which has been sedimented without any previous treatment has a number average molecular weight (M_n) equal to 68.2×10^6 daltons. Exposure of DNA to 0.15 M NaOH for 5 min at 20 °C, before sedimentation causes M_n to drop to 45.6×10^6 daltons and the profile becomes less heterogeneous. Figure 1b shows that the same treatment on T4 DNA produces no change in the sedimentation profile; T7 DNA displays exactly the same behaviour (results not shown). The results of several experiments similar to that shown in Fig. 1a are given in Table 1. The average number of alkali-sensitive linkers for five different determinations (a–e) was 0.87 ± 0.29 per 10^8 daltons. This means that an average of one linker is found for every 115×10^6 daltons. In one case (Table 1e) the NaOH treatment was more drastic, without introducing comparatively more breaks, therefore, the more gentle reaction condition seems to give a full account of the linker disruption. In two other experiments (Table 1f,g) DNA was pulse-labelled for 25 min and the number of breaks observed was larger than in DNA labelled for several hours; other experiments are needed to define whether these results reflect a modification of the frequency of linkers as the DNA matures.

In opposition to the linker hypothesis, it could be argued that formamide does not render the DNA completely denatured, and that this is only accomplished after treatment with NaOH. This seems not to be the case, however, since T4 DNA displays the same sedimentation profile with or without NaOH treatment. Further evidence that DNA is already denatured before NaOH treatment is given by the experiment of Fig. 2. In this experiment, we intended to produce a DNA in which the opposite strands were labelled differently and had different sizes. If, on centrifugation in formamide, we obtained separation of the two sedimentation profiles we could conclude that the DNA was denatured. Cells were therefore prelabelled with ^{14}C -thymidine for 48 h and then pulse-labelled with ^3H -thymidine for 25 min. In these conditions, long strands of ^{14}C -labelled parental DNA should be hydrogen bound to strands of ^3H -labelled, newly synthesised DNA. This latter should be more heterogeneous in size, because it corresponds to growing strands of all sizes between zero and the size of the replicating unit^{5,6} (about 10^8 daltons). Denaturation is thus denoted in this experiment by the separation of the two profiles, in a situation essentially identical to that obtained in alkaline sucrose gradients⁹.

We conclude from these results that the DNA molecules from African green monkey kidney cells contain linkers that are sensitive to alkali and that they are, on average, located 115×10^6 daltons apart. The nature of these linkers is now being investigated and two main possibilities are

Fig. 2 Strand separation in sucrose-formamide gradients. The cells were incubated in ^{14}C -thymidine ($0.1 \mu\text{Ci ml}^{-1}$) for 48 h. The medium was withdrawn and the cells incubated for 25 min in $50 \mu\text{Ci ml}^{-1}$ ^3H -thymidine. The DNA was extracted, centrifuged, fractionated and counted as described in the legend of Figure 1. \square , Percentage of ^{14}C -DNA, $M_n = 62.8$; \blacktriangle , percentage of ^3H -DNA, $M_n = 20.5$.

being pursued, namely, a ribonucleotide linker and an apurinic and/or apyrimidinic site.

Ribonucleotides have been detected in mature closed-circular mitochondrial DNA¹⁻³. Their presence could be envisaged as due to insertion into DNA during replication by a relatively non-stringent DNA polymerase or that they are remnants of RNA primers which have not been completely excised. Substantial evidence has been presented from several systems that an RNA polymerase product provides the 3'-hydroxy primer required by all known DNA polymerases⁷⁻⁹. Apurinic sites are known to be formed spontaneously in DNA at a rate corresponding to 5×10^{-2} depurinations per 10^8 daltons per h at 37 °C (ref. 10). Table 1 shows that the linkers are already present at a frequency of 1.5 per 10^8 daltons in short pulse-labelled DNA, therefore, apurinic/apyrimidinic sites could only have been introduced catalytically, such as by a base alkylation mechanism.

Several laboratories have reported that treatment of cell lysates with proteases before centrifugation in alkaline sucrose gradients decreased the size of the DNA molecules¹¹⁻¹³. After the treatment, single-strand pieces of 60×10^6 , 45×10^6 and 6×10^6 daltons were observed in CHO (ref. 11), mouse L cells¹² and Ehrlich ascites tumour cells¹³, respectively. The connection between these results and ours is not clear as yet. A preliminary experiment in which NaOH was replaced by proteinase K did not show any reduction in the molecular weight. It is possible that the protease treatment of the cell lysates removed protein from the DNA rendering the linkers accessible to the alkali. In our experiments, these proteins would have been extracted by the phenol-chloroform treatment and so

Table 1 Number of single-strand breaks produced in DNA on treatment with sodium hydroxide

Experiment	M_n untreated	M_n treated	No. of breaks per 10^8 daltons	Treatment
a	71.9	49.7	0.62	0.15 M NaOH, 10 min, 20 °C
b	66.7	42.4	0.86	0.15 M NaOH, 5 min, 20 °C
c	78.3	38.4	1.32	0.15 M NaOH, 5 min, 20 °C
d	68.2	45.6	0.73	0.15 M NaOH, 5 min, 20 °C
e	71.9	45.2	0.82	0.50 M NaOH, 1 h, 37 °C
f	42.7	26.7	1.40	0.15 M NaOH, 10 min, 20 °C
g	42.7	25.3	1.61	0.50 M NaOH, 1 h, 37 °C

a–e, DNA was labelled with radioactive thymidine for periods varying from 8 to 48 h. In f and g DNA was pulse-labelled for 25 min only. Determination of M_n is described in the legend to Fig. 1. Alkali treatment varied as indicated. The number of single-strand breaks was calculated using the expression $(M_n \text{ treated}/M_n \text{ untreated}) - 1$. The values were normalised to 10^8 daltons.

the alkali-sensitive sites would already be accessible to attack.

Chloramphenicol-sensitive labelling of protein in microsomes of *Neurospora crassa*

SEVERAL peptides are synthesised on mitochondrial chloramphenicol-sensitive ribosomes¹. In the presence of cycloheximide ($\sim 200 \mu\text{g ml}^{-1}$), amino acids are incorporated exclusively into mitochondrial proteins in *Neurospora crassa*² and the flight muscle of *Locusta migratoria*³, leading to the generally accepted idea that mitochondrially synthesised proteins remain in the mitochondria. It is possible, however, that the high concentration of cycloheximide used in those experiments could inhibit any potential export of such proteins to other parts of the cell, particularly since the drug has been shown to affect several vital cellular processes independently of its effect on protein synthesis; for example, it stimulates the catabolism of nucleic acids and decreases intracellular ATP (ref. 4). This may explain some published indications of export of mitochondrially synthesised proteins in experiments in which cycloheximide was not used, such as the continued synthesis of myelin proteolipid in crude mitochondrial fractions of rat brain homogenates treated with RNase⁵; and the cytoplasmic location of the mutation in a line of *Zea mays* responsible for the susceptibility of its root plasma membrane K^+ -stimulated ATPase to the toxin of *Helminthosporium maydis* race T.⁶ We describe here observations on the incorporation of radioactivity into membranes of the post-mitochondrial supernatant of homogenates of *N. crassa* which had been pulsed with radioactive amino acids in the presence of cycloheximide ($25 \mu\text{g ml}^{-1}$) then grown for 2 h in drug- and label-free medium. We have been unable to account for this solely on the basis of mitochondrial fragmentation. Of the membranes present in the postmitochondrial supernatant, we have investigated in detail a microsomal fraction enriched for endoplasmic reticulum, as a first step in determining the nature of this incorporation.

N. crassa 74A was cultured and pulse-chase labelled with amino acids in the presence of selective inhibitors of pro-

tein synthesis. Microsomes and mitochondria were isolated as described in the legend to Fig. 1, and the two fractions characterised by marker enzyme assays. The microsomal fraction was enriched 10-fold over the mitochondria in glucose-6-phosphatase activity measured according to de Duve *et al.*¹⁰, and no haem *a* was detectable in reduced minus oxidised difference spectra¹¹. The assays indicated that the microsomes were enriched in endoplasmic reticulum and virtually devoid of mitochondrial inner membrane.

Four proteins whose synthesis is chloramphenicol-sensitive are normally obtained from pulse-labelled *N. crassa* mitochondria. Their molecular weights are roughly 10,000, 20,000, 30,000 and 40,000. The 10,000 molecular

Fig. 1 Distribution of radioactivity in *a*, microsomes and *b*, mitochondria. *N. crassa* was labelled as described previously⁷, except that 200 μCi of $[\text{G-}^3\text{H}]\text{L-phenylalanine}$ (Schwarz-Mann, 10 Ci mmol⁻¹), per 500 ml of medium was routinely used in place of leucine as the labelling agent. In one series of experiments the cultures were labelled with 500 μCi ^3H -amino acid mixture (Amersham/Searle code TRK.440) per 600 ml of medium. The cells were labelled in the presence of cycloheximide ($25 \mu\text{g ml}^{-1}$) or cycloheximide ($25 \mu\text{g ml}^{-1}$) plus chloramphenicol (4 mg ml^{-1}). Mycelial pads were collected by vacuum filtration and disrupted in a mill (B. Braun, Melsungen) with 0.5-mm glass beads in the following buffer: 0.5 M sucrose, 1 mM EDTA, and 50 mM Tris-HCl, pH 7.5. To inhibit protease activity, 0.5 mM phenylmethylsulphonyl fluoride was added to all buffers. Nuclei and the bulk of the cell wall were removed by centrifugation at 2,000g for 10 min, and a heavy mitochondrial fraction was obtained by centrifugation of the supernatant at 8,000g for 15 min. The mitochondria were washed by homogenising in the same buffer, and repeating the above centrifugations. Light mitochondria and lysosomes were removed from the postmitochondrial supernatant by centrifugation at 50,000g for 30 min, and discarded. Microsomes were then prepared by centrifuging the supernatant at 105,000g for 1 h. The pellet was washed by resuspension in the same buffer, followed by centrifugations at 50,000g and 100,000g. All operations were carried out at 0–4 °C. Protein was measured by the method of Lowry *et al.*⁸. Microsomes and mitochondria were assayed by SDS-polyacrylamide gel electrophoresis in sodium dodecyl sulphate, using 11.5% gels as described by Fairbanks *et al.*⁹, as modified by Lansman *et al.*⁷. The radioactivity in 2-mm gel slices was measured by liquid scintillation counting after swelling in 0.4 ml NCS Tissue solubiliser (Amersham/Searle) for 2.5 h at 45 °C followed by addition of toluene plus Omnifluor (Packard). *a*, 100 μg sample of microsomes; *b*, 100- μg sample of mitochondria; \circ , cycloheximide; \times , cycloheximide plus chloramphenicol.

Fig. 2 Determination of the apparent molecular weight of CSMP. Microsomes (650 μ g), labelled in the presence of cycloheximide as described in Fig. 1, were extracted with chloroform-methanol (2:1) centrifuged at 5,000g for 10 min and the supernatant dried under nitrogen. The residue was electrophoresed in SDS-urea polyacrylamide gels according to Swank and Munkres¹². Radioactivity was determined as described in Fig. 1. The position of markers was determined after staining with Coomassie Blue¹².

weight (MW) peak disappears from mitochondria after a 2-h chase period⁷. In experiments reported here, equal quantities of mitochondrial and microsomal protein (100 μ g per gel) from cells pulse-chase labelled in the presence of cycloheximide or cycloheximide plus chloramphenicol were compared by sodium dodecyl sulphate (SDS)-polyacrylamide gel electrophoresis. The distribution of radioactivity in mitochondria and in microsomes from cells pulse-chase labelled in the presence of cycloheximide alone showed distinct differences (Fig. 1). The mitochondria had little protein of MW about 10,000 and none smaller than this, as expected for *N. crassa* mitochondria labelled in this manner⁷. In contrast, the majority of the radioactivity in the microsomes appeared in a low MW protein which was smaller than the 10,000 MW protein seen in mitochondria after a pulse-label experiment, and is therefore unlikely to be derived from mitochondrial membrane fragments. The synthesis of the microsomal protein was reproducibly sensitive to chloramphenicol. The apparent MW of this chloramphenicol-sensitive microsomal protein (CSMP) as determined by polyacrylamide gel electrophoresis in the presence of SDS-urea was 5,000 to 8,000 (Fig. 2). CSMP was readily extractable from microsomes with 20 volumes of 80% acetone or with chloroform-methanol (2:1), the latter property suggesting it is a proteolipid.

Saponification of chloroform-methanol extracts of microsomes labelled in the presence of cycloheximide, which should release any amino acids present as amino-lipids, revealed negligible amounts of radioactivity recoverable as amino acids, suggesting that the bulk of the radioactivity was incorporated into protein. Only 6% of the radioactivity was recovered in petroleum ether extracts after saponification of ³H-phenylalanine-labelled CSMP, indicating a low level of amino acid conversion to lipid. Total acid hydrolysis of CSMP was obtained only after saponification, however, suggesting that the peptide chain may have been protected to some degree by lipids. Labelled phenylalanine (as assayed by thin-layer chromatography) was recovered from total acid hydrolysates of CSMP isolated from cells pulse-labelled with ³H-phenylalanine (Fig. 3a). Several different amino acids were detected by ninhydrin visualisation and radioactivity in total hydrolysates of CSMP isolated from cells labelled with a mixture of ³H-amino acids (Fig. 3b).

Thin-layer chromatography of chloroform-methanol extracts of microsomes or mitochondria in a system that separates a variety of lipids gave a band of radioactivity whose synthesis was chloramphenicol sensitive. This band

migrated with an R_f similar to that reported for a low molecular weight proteolipid synthesised by isolated rat liver mitochondria^{15,16}, and which is similar to the R_f of phosphatidyl choline (Fig. 4a and b). The acid hydrolysis data described above, however, indicated that the radioactivity was recovered in amino acids, not in phosphatidyl choline. Phosphatidyl serine, the most common amino-lipid, migrates with an R_f close to 0.4 in the first developing system. Thus, the radioactivity in CSMP could not be due to label converted to phosphatidyl serine.

All the above data suggest very strongly that CSMP is indeed a protein, albeit with somewhat unusual properties.

Fig. 3 Analysis of total hydrolysates of chloramphenicol-sensitive cycloheximide-insensitive material by thin-layer chromatography. *N. crassa* microsomes labelled in the presence of cycloheximide with: a, [³H] phenylalanine (see Fig. 2) or b, ³H-amino acid mixture (as described in the text) were extracted in chloroform-methanol (2:1) and dried under nitrogen. The dried residues were saponified in 95% methanol, 0.5 M NaOH at 30 °C for 15 h, acidified to pH 3 with 6 M HCl and extracted three times with 2 vol. petroleum ether which removed non-saponifiable lipids. The methanolic layer was neutralised, dried under N₂ and hydrolysed in 6 M HCl at 110 °C for 72 h. HCl was removed in a vacuum dessicator over NaOH and concentrated H₂SO₄. The residues were dissolved in water and desalted, using a Dowex-2 (AG-2 X-10, BioRad) anion exchange resin (which also removed ethanolamine and choline)¹³ followed by removal of HCl and acetic acid by vacuum desiccation as above. Amino acids were separated on silica gel plates (EM Laboratories), with ethanol-water (7:3), and visualised with ninhydrin (shown as cross-hatched spots below the graphs). The radioactivity was determined by liquid scintillation counting of 0.5-cm bands in Bray's solution¹⁴.

Fig. 4 Thin-layer chromatography of chloroform-methanol extracts of subcellular fractions. *a*, Microsomes and *b*, mitochondria were isolated from *N. crassa* pulse-chase labelled in the presence of cycloheximide or of cycloheximide plus chloramphenicol. Membrane suspensions (146 μ g protein) were extracted with 1 ml of chloroform-methanol (2:1) at room temperature for 10 min followed by centrifugation at 5,000g for 10 min. The supernatants were dried under nitrogen, dissolved in a small volume of the same solvent, and separated by thin-layer chromatography on silica gel HR (Merck). Phospholipids and neutral lipids were separated by successive developments in chloroform-methanol-glacial acetic acid-water (65:25:8:4) (ref. 17) and then petroleum ether-diethyl ether-glacial acetic acid (75:25:1) (ref. 18). Lipids were visualised with iodine vapour (shown as cross-hatched spots below the graphs). Bands (0.5 cm) were scraped from the plate into counting vials, and radioactivity was determined by counting in toluene-liquifluor (New England Nuclear) using a Packard Tri-Carb liquid scintillation counter. Standards were: LEC, dipalmitoyl lecithin; G, gramicidin D; E, ergosterol; FA, oleic acid; TG, triolein. Cycloheximide, hatched; cycloheximide plus chloramphenicol, solid.

Purification of this protein is in progress. After gel filtration of the chloroform-methanol soluble fraction of *N. crassa* microsomes on LH-20 columns, a single radioactive ninhydrin-positive spot is observed on paper chromatography.

The appearance of the protein CSMP in the microsomal fraction could be explained in several ways. As shown above, it is unlikely to be due to simple cross-contamination from mitochondrial inner membranes. The results could be accounted for by CSMP escaping from the mitochondria during the isolation procedure, but a very hydrophobic protein such as this is unlikely to be removed from mitochondrial membranes in the isolation conditions used. It is unlikely that CSMP is the result of labelling of microsomal protein(s) by a non-ribosomal-dependent enzyme

system insensitive to cycloheximide but sensitive to chloramphenicol as has been reported for *in vitro* preparations of myelin¹⁹. In the conditions used for *in vitro* incorporation of radiolabelled amino acids into a myelin fraction¹⁹, no chloramphenicol-sensitive incorporation of ³H-phenylalanine by a 20,000g supernatant of an *N. crassa* homogenate was found. The only labelling observed was sensitive to cycloheximide and insensitive to chloramphenicol, suggesting normal *in vitro* cytoplasmic ribosomal-dependent incorporation of amino acids. These observations are in direct contrast to the *in vivo* labelling pattern of CSMP, supporting our contention that CSMP is synthesised on chloramphenicol-sensitive ribosomes and not by an unusual enzymatic reaction sensitive to chloramphenicol. It is possible that there are hitherto undescribed cycloheximide-insensitive, chloramphenicol-sensitive ribosomes outside the mitochondria. It is also possible that CSMP is a product of mitochondrial protein synthesis which has been processed during or after export. In summary, the evidence is most consistent with CSMP being synthesised on mitochondrial ribosomes and exported from the mitochondria.

Preliminary experiments with isolated rat hepatocytes have indicated that export of low molecular weight proteolipids from mitochondria to the endoplasmic reticulum and also to the plasma membrane occurred.

The role or roles of CSMP in the cell are unknown. Several investigators have concluded mitochondrial export to the cytoplasm must exist. Some of these reports suggest a repressor function for this protein. Barath and Kuntzel²⁰ observed that in the presence of chloramphenicol or ethidium bromide, an increased biosynthesis of certain nuclear gene products associated with the *Neurospora* mitochondrial transcriptional and translational apparatus occurred. A model was proposed for a mitochondrial repressor which regulates the synthesis of these proteins. Such a repressor has also been proposed by Edwards *et al.*²¹ to explain a similar chloramphenicol effect on the induction of the cyanide-insensitive alternate oxidase of *Neurospora*, an enzyme that is synthesised in the cytoplasm. This repressor model could also explain the induction of the alternate oxidase in the mitochondrial mutants *mi-1* and *mi-3* of *Neurospora*²².

Export of mitochondrial protein could be the functional basis for a mitochondrial linkage to cellular transformation. This is suggested by the protection of BALB 3T3 cells from viral transformation by pretreatment with ethidium bromide²³, by the close correlation of the severity of granulocytic leukaemia with the frequency of circular dimers of mitochondrial DNA in leukocytes²⁴ and by the distinct and specific changes in the synthesis of mitochondrial DNA in chick embryo fibroblasts transformed by Rous sarcoma virus²⁵.

A cholesterol-isopropanol gel

IN the course of measuring solubilities of cholesterol in pure and mixed solvents we have observed the formation of a transparent gel in the cholesterol+isopropanol system. Because of the historical importance of liquid crystals of cholesteryl esters¹ and the biological importance of cholesterol, we are reporting here some observations on the properties of this gel. Liquid crystals of cholesterol with fatty alkanols (C₁₂–C₁₈) are known^{2,3}, but have not been reported for smaller alcohols. The transparent gel of cholesterol and isopropanol seems to be stable at 4 °C for concentrations of 4.6–5.3% (w/w) cholesterol. At higher concentrations and temperatures (up to 10.2% at 22 °C), the transparent gel can be observed for a day or more, then white 'snowflakes' appear throughout the gel and grow slowly into a translucent or opaque mass. On warming, the transparent gels liquify, and the translucent gels seem to go directly to the liquid state. The transparent gel is unstable to vigorous shaking; samples with less than 5.5% cholesterol liquify then return to the transparent gel state on standing at 4 °C. Samples with larger concentrations form the translucent or opaque state on shaking and do not return to the transparent state over a period of several weeks. Observations of the transparent gel under a polarising microscope at room temperature showed the sample to be mostly isotropic with some small points of optical activity.

Cholesterol (Fisher Certified Reagent Grade) originally with a melting point of 147–148 °C. After several recrystallisations from ethanol the melting point was 148–149 °C. Isopropanol (Matheson, Coleman and Bell Spectroquality) was stored over molecular sieves and twice distilled, retaining the middle one-third each time. In all of the measurements reported here, these purified materials were used, but very similar results were obtained with untreated materials. Samples were prepared by weight, sealed in glass ampoules under reduced pressure, warmed to dissolve the solid, and then allowed to stand without shaking in four different environments ranging from –10–22 °C, all with observed temperature fluctuations of about 1 °C. Four physical states were observed: liquid, transparent crystalline plates, transparent gel, and the white material which seems to be an amorphous solid dispersed throughout the gel. Our observations are shown in Table 1.

After initial preparation, the gel took 2–3 d to form. If the gel was broken by shaking or slight warming, it reformed in a matter of minutes to hours, but if warmed excessively gel formation required several days. The upper surface of the gel was always coated with a small amount of liquid, presumably due to temperature fluctuations and handling. In one case, however, (4.62% cholesterol at 4 °C) substantial amounts of the liquid and gel phases can coexist.

Table 1 Coexisting states in the cholesterol-isopropanol system

% Cholesterol (w/w)	–10 °C	4 °C	18 °C	22 °C
4.03	L+P	L	L	L
4.16	L+P	L	L	L
4.62	L+P	L+P+G	L	L
5.29	L+P	P+G	L	L
5.49	L+P	P+G+W*	L	L
6.69	W	W	W	L
7.61	W	W	W	W
11.66	W	W	W	W†

L, Liquid; P, crystalline plates; G, transparent gel; W, white mass.

*Small flakes of white appeared in the transparent gel after approximately one week, and seemed to be slowly increasing in size.

†This sample liquified at 43 °C.

Samples with 6.69% or more cholesterol form the white mass at –10 °C, but it is unlikely that this is an equilibrium state. There seems to be kinetic competition between formation of the white material and formation of the crystalline plates. Samples of 5.49% and 6.69% cholesterol were allowed to gel at 4 °C, both with a small amount of white 'snowflakes'; the 5.49% sample also contained some transparent plates. When these samples were moved to the –10 °C environment, the less concentrated sample formed plates with liquid, and the more concentrated sample formed the white mass, possibly containing some crystallites.

To find out more about the white materials we have observed, we have begun measurements of the weight gain of cholesterol on exposure to isopropanol vapours. We have observed a gain corresponding to 1.9 molecules of isopropanol per molecule of cholesterol above pure liquid isopropanol, and some of our measurements indicate that the ratio of 0.5 isopropanol molecules per cholesterol molecule may be a stable configuration.

Garner, *Nature* **267**, p. 865, the legend to Fig. 1, line 14 should read . . . To this two-phase system was added 1.25 mg 3-chloro-perbenzoic acid (4 molar excess) and the whole stirred for 25 h at room temperature in the dark in a stoppered flask.

In the letter 'On the optical identifications of five X-ray sources' by H. V. Bradt *et al.*, *Nature*, **269**, p. 21, the last line of the abstract should read . . . suggested class of Be-star X-ray emitters.

reviews

Reproductive physiology in the male

B. P. Setchell

The Process of Spermatogenesis in Animals. By Edward C. Roosen-Runge. Pp. viii+214. (Cambridge University: Cambridge, London and New York, 1977.) £15.50.

THIS book is an extremely welcome addition to the literature on reproduction in the male. It brings together an absolute wealth of information on the formation of spermatozoa in lower animals and then relates this to the much greater body of knowledge about testis function in mammals. The book begins with a historical introduction, important in a subject which has developed explosively in the last ten years. The author then works systematically through the Animal Kingdom, collating and tabulating the widely scattered information, and more importantly, discussing its relevance to the situation in other classes of animals. As a scientist working on the physiology and biochemistry of the testis in mammals, I found the book extremely interesting and stimulating.

The invertebrate species, in particular, provide so many extraordinary variants on the basic theme that I will look with new eyes at my own data to see whether things in mammals are as simple as they have seemed till now. I found the description of the 'carrier' spermatozoa in the marine snail *Janthina* particularly intriguing, as was Professor Roosen-Runge's own work on the marine hydrazoon *Phialidium*. This animal releases spermatozoa twice daily at sunrise and sundown for 3-4 months and its testes continue to produce and release spermatozoa *in vitro* although in these conditions spermatogonia are not renewed. This animal should obviously be studied in greater detail in view of the failure so far to maintain spermatogenesis, particularly the meiotic divisions, in cultures of fragments of mammalian testes.

I am not quite so sure whether a zoologist, who wanted to obtain a general picture of reproduction in male mammals to relate to the animals he was studying, would find all the information he needed. Professor Roosen-Runge is one of the most imaginative of the still-active older scientists in this field and he has worked for many years on spermatogenesis in mammals, although his contribution is often underrated. It is therefore a pity that

he feels that this field "has been reviewed almost to excess" and does not attempt a detailed exposition of his view of the present state of knowledge of mammalian spermatogenesis.

The book is very well produced, although I do find it irritating that the plates are grouped together rather than spaced through the text, but I suppose that this is a consequence of rising costs. There seem to be very few spelling mistakes (even fewer if the 'bettle' on p70 is not meant to be a 'beetle'). Some of the line drawings could be clearer and several are inadequately labelled, for example Fig. 3

(p7), in which the numbers are undefined and cannot be reconciled easily with the text.

In summary, this is a book which every library interested in the physiology of reproduction should have; and almost all workers in this field would learn something new by reading it. Professor Roosen-Runge is to be congratulated. I do not know of anyone else who could have done it as well. □

Human variation and adaptation

Population Structure and Human Variation. International Biological Programme. Vol. 11. Edited by G. A. Harrison. Pp. 342 (Cambridge University: New York, London and Cambridge, 1977.) £17.50.

THIS monograph consists of a selection of studies of human populations carried out during the International Biological Programme. Each of the 12 chapters attempts a broad review of investigations concerned with population genetics, demography and ecology as they relate to human variation and adaptation.

In the past, physical traits (such as head shape and skin colour) have been largely used for defining population groups, but the value of such traits is somewhat limited because they are polygenically determined, and at least some are significantly affected by the environment. For these reasons anthropologists and population geneticists have increasingly turned their attention in recent years to monogenically determined biochemical markers (blood groups, haemoglobins, serum proteins and enzymes) and it is with the distribution of these markers, as well as disease incidences and various physiological parameters, that this book is also concerned.

The world distribution of genetic markers is reviewed and also the findings in various "isolates" in North Asia, the Yanomama Indians of Brazil and the Solomon Islanders. The nature of specific factors which may influence

human variation and adaptation are also approached through the study of migration of genetically similar groups into different environments (Tokelau Islanders of the Pacific into New Zealand, the African savanna dwellers into the equatorial rain forests) the study of genetically different groups living in similar environments (various Jewish communities in Israel) and physiological adaptations to extreme environments (the semi-arid regions of Central Africa and the tropical forests of Papua New Guinea).

There are those who might question the merit of studying the frequencies of various traits in different populations which, at their lowest level, Mall the anatomist might somewhat irreverently have referred to as 'brick-counting-research'. But in defence of such studies it can be asked how else can human evolution and adaptation be investigated? If there is a defect perhaps it lies not so much in the collection and analysis of such data but rather in their interpretation.

This is essentially a postgraduate text, and in any event is far too expensive for possible recommendation to undergraduates. It is well edited and presented, and should prove particularly valuable for research workers. It is also an excellent sourcebook of relevant data for teachers of human biology, population genetics and anthropology.

Alan E. H. Emery

Alan E. H. Emery is Professor of Human Genetics at the Medical School, University of Edinburgh, Scotland, UK.

Crystal structure compendium

Three-Dimensional Nets and Polyhedra.

By A. F. Wells. Pp. 268. (Wiley Interscience: New York and London, 1977.) £22; \$36.

WE are much indebted to A. F. Wells for his massive volumes of *Structural Inorganic Chemistry* which systematise the spatial arrangements of atoms in crystalline inorganic solids. Professor Wells has now taken the topological material involved in these structures and examined it in greater detail.

He considers primarily nets which are periodic in three dimensions. These are characterised topologically with symbols derived from those of Schläfli: the indices (p, q) meaning that q links meet at each point and that the shortest circuits including any pair of links from a point have p edges. This symbol he finds to be inadequate for complete description, and further numbers are added, although it is not perhaps easy enough for the reader to grasp the significance of the sub- and superscripts, especially when dipping into the book. Perhaps about a hundred different nets are considered so that the subject is a considerable test of the spatial imagination. As Wells admits, the various structures which he describes are difficult to apprehend and the building of models is recommended to supplement the stereo photographs provided. The latter are not very successful because the screen pattern becomes intrusive when they are magnified by a stereo-viewer.

The most interesting section is on infinite polyhedra, the simplest of

which were discovered by Petrie and Coxeter in 1926. These can be obtained by inflating the links in a network until they become tubes. The resulting surface is then tiled with polygons. Such polyhedra divide space into two regions. Some molecular sieve crystals are of this type. It is clear that these figures are just the first of a hierarchy, and they begin to hint at the development of 'biogeometry', which may describe structures such as membranes, micelles, butter, the frameworks observed by electron microscopy in wood, moving up to cell organelles, and so on.

There is scope for the development of the notation and presentation of data on these networks and there are further topics, especially that of random networks, which we would like to hear about, but which the author has consciously eschewed.

The constraints which sheer topology imposes on spatial structure are remarkably strong, both in detail for atomic networks and statistically, as in the phase rule of physical chemistry. Wells has made a start on the systematisation of important structural invariants and it is to be hoped that this will eventually lead to their more complete characterisation, such as has been done for the symmetry groups by the International Tables for X-ray Crystallography. Until such time, Wells' compendium will be of value to those dealing with crystal structures and suggestive in many other areas concerned with three-dimensional structure.

A. L. Mackay

A. L. Mackay is Reader in the Department of Crystallography at Birkbeck College, University of London, UK.

Computational fluid dynamics

Numerical Methods in Fluid Dynamics. By Maurice Holt. Pp 253. (Springer: Berlin and New York, 1977.)

THIS monograph is based on lectures from a course for graduate engineers. The emphasis is on methods developed in the USSR. For problems governed by hyperbolic partial differential equations, methods attributable to Godunov, the BVLR method, and methods using the theory of characteristics are described. The number of application studies is noticeably smaller in chapters dealing with hyperbolic problems than is the case for the later chapters dealing with the method of integral relations, Telenin's method, and the method of lines.

More than half of the book is devoted to applications of the method of integral relations, Telenin's method, and the method of lines to flows described by elliptic, parabolic, or mixed elliptic/hyperbolic partial differential equations. Two-dimensional incompressible flow problems, problems associated with blunt bodies at incidence, three-dimensional cone-field problems, and viscous laminar boundary layer problems are amongst those considered. The detailed explanations of the implementation of the methods and the many specimen results, should make it relatively easy for the inexperienced to use the methods described.

The careful presentation of variations on methods for the successful solving of particular problems, and the many references ensure that the monograph will be a welcome addition to the computational fluid dynamics literature. The text can readily be understood by anyone having a basic knowledge of the equations governing fluid flow. It will be useful both to graduate students in engineering or applied mathematics and to research workers.

Professor Holt's monograph is, however, not a model work. More authoritative criticisms of methods, together with results demonstrating the breakdown of methods, would have been desirable to avoid giving the reader the unfortunate impression that he has been provided with infallible recipes which can be used to solve any given problem.

F. Walkden

F. Walkden is Director of the Fluid Mechanics Computation Centre at the University of Salford, where he is Professor of Applied Mathematics.

Arab survey

Scientific Results of the Oman Flora and Fauna Survey 1975. A Journal of Oman Studies Special Report. Introduced by David L. Harrison. Pp. 267. (Michael Rice: London; Ministry of Information and Culture: PO Box 600, Muscat, Sultanate of Oman, 1977.) \$10; Rials Omani 5.

THE change in fortune of the peoples of Arabia are the talk of the world today: less well known are the peninsula's untrampled desert plains and mountains which are among the few wilderness areas left on earth for scientists to explore. For example the Sultanate of Oman in south-eastern Arabia, with its backbone of mountains up to 3,000 m high, offers unique oppor-

tunities for naturalists to record plant and animal life in habitats which until a few years ago were largely inaccessible.

Oman is in a critical zoogeographical position between Eurasia and Africa and also offers in the cooler highlands of its northern parts an environment in which relict forms have survived from more temperate conditions. This useful survey, the first of its kind to be carried out in the country, has provided many species and forms new to science and has laid the foundations for conservation programmes in the Jabal Akhdar and Jabal Aswad ranges where the rare Arabian tahr (*Hemitragus jayakari*) still survives. **Sarah Bunney**

Sarah Bunney, a zoologist, recently returned from Oman, where she spent two years working as librarian for the Omani Ministry of Health.

Control of eye movements

The Theory of Binocular Vision. By E. Hering. Edited by B. Bridgemann and Lawrence Stark. Pp. 218. (Plenum: London and New York, 1977.) \$29.40.

THIS admirable translation of Hering's monograph on the control of eye movements will be of unfaded value to present-day workers in the field; but it will also interest historians of science, for Hering prepared his monograph largely in response to Helmholtz's *Physiological Optics*, and it illustrates the nature of the systematic controversy between the two physiologists. The translation will help to dispel the two textbook myths, that Hering eschewed detailed experiments and that he adopted a rigidly nativist position; and it serves to emphasise how much Helmholtz and Hering shared—common problems, common assumptions, common experimental techniques and common criteria for the acceptability of evidence.

Central to the monograph are the

idea that the two eyes should be treated as a single organ (the *Doppel-auge*) and the principle that corresponding muscles are always equally innervated, whatever the initial position of the eyes before a movement (Hering's Law). In opposing the Helmholtzian view that the two eyes come to be used together only by habit, Hering is led to discuss the movements of occluded, suppressed and blinded eyes; asymmetrical vergence movements; cases of unilateral paresis of eye muscles; and the coordination of the eyes in infants.

B. Bridgemann's translation is both careful and readable (although some obscurities survive in chapter 17) and he has added a helpful Introduction. L. Stark has independently provided summaries and commentary interleaved in the main text. Internal evidence suggests a curiously strained relationship between the two editors and this is to be regretted, for the task was a very worthwhile one. **J. D. Mollon**

J. D. Mollon is Lecturer in Experimental Psychology at the University of Cambridge, UK.

Inhomogeneous optical waveguides

Inhomogeneous Optical Waveguides. By M. S. Sodha and A. K. Ghatak. Pp. x+269. (Plenum: New York and London, 1977.) \$35.40.

ELECTROMAGNETIC THEORY as formulated by Maxwell has been with us for a good hundred years but the interest in it has shown no signs of abating. New potential applications (in this case the promise of optical communications) have brought the need for new analyses which after a period of digestion could be profitably presented in book form. The authors of this book are particularly suited for the task of writing on inhomogeneous optical waveguides since they have themselves written no less than twenty papers on the subject. The product is a book which anyone interested in the mathematical approaches is well advised to study. Apart from a few omissions (for example, the complex ray method) the authors provide a detailed and interesting review.

The strength of the book lies in giving copious answers to the question 'how to solve it?', its weakness is that the equally important question of 'what is it good for?' is sadly neglected. After all, the sole justification for the existence of these waveguides

is that they can perform some useful function. An engineer would like to know why certain structures have been chosen, what are their comparative advantages and disadvantages, and would like to see the conclusions presented in simple form. Unfortunately, this kind of discussion is entirely missing and 25-page appendix on manufacturing techniques is hardly a compensation for it. The descriptions are so sketchy and the links with the calculations so tenuous that they could have been replaced by a list of references.

There are also some minor inconsistencies in the presentation. For example, under the heading of "General Theoretical Considerations" in section 2.2, the particle current is taken as zero and the solution in section 2.3 is obtained on that assumption. In section 2.4, however, complex dielectric constants suddenly appear, and the reader is told without any explanation that the real part of the dielectric constant of a metal is negative. Such minor flaws are likely to confuse undergraduates and less well equipped graduate students. On the whole, however, the book may be recommended to those already familiar with a wide range of electromagnetic problems and wishing to move into this new field.

Cell and tissue proteinases

Proteinases in Mammalian Cells and Tissues. Edited by A. J. Barrett. Pp. xx + 735. (North-Holland: New York, Oxford and Amsterdam, 1977.) Dfl. 196; \$79.95.

THE scope of this long and expensive book is somewhat wider than is indicated by its title because two of its sixteen chapters deal with proteinase inhibitors and another is devoted to synthetic substrates and inhibitors. In addition, the properties of the plasminogen activators of plasma, tissue and urine are described in an interesting chapter by Christman, Silverstein and Acs, who emphasise that neither the source of the plasminogen activators of the plasma, nor the identity of these enzymes with their tissue counterparts, can be stated with certainty.

Evidently, it is difficult to decide on all the enzymes which should be considered to be either cell or tissue proteinases. Undoubtedly, however, the decision to include consideration of certain plasma constituents has proved fruitful because, without data of this kind, discussion of the physiological roles of the cell and tissue proteinases would be difficult. The discussion of some aspects of how the tissue proteinases may be expected to function *in vivo*, such as whether plasminogen activators are important in tumorigenesis and wound healing, is speculative, but the inclusion of these concepts adds greatly to the interest of the book.

The rapidity at which information on tissue proteinases has accumulated since 1975 is mentioned in the preface. It is indeed remarkable that, whereas only six enzymes were dealt with in a similar book published in that year, details of seventy-one are to be found in the present volume. The introductory chapter by Barrett on the history and classification of the tissue proteinases helps to clarify the subject. By way of an extra, it is interesting to learn that Darwin in 1875 was the first to pose the question of the evolutionary relationship of the proteinases of plants and animals.

Perhaps because of the importance of elastase and Cathepsin G in inflammation the first chapter by Starkey is devoted to the methods of isolation and properties of these two enzymes which together have been shown to be capable of hydrolysing all the major tissue proteins. Particularly when extracellular (as, for instance, at the start of inflammation and thus not subject to the same degree of inhibition by α_2

macroglobulin or α_1 antitrypsin), these enzymes have been shown to be capable of digesting immune complexes and probably of playing a part in combating bacterial infection. These findings are mentioned mainly as an example of the mass of detailed information which has been brought together in this book. Undoubtedly the efforts of the many contributors have resulted in a volume which is both stimulating and will remain as a useful source book.

It is a pleasure to be able to report that there are few errors: in fact only one of any importance has been detected by the reviewer. This concerns the α_1 and α_2 macroglobulins of rabbit and rat. Unfortunately on p670, lines 7 and 8, the subscripts have been transposed. This is of some importance because as printed the impression is

given that α_2 macroglobulin of rabbit and α_1 macroglobulin of rat increase in concentration during inflammation. In fact, it is the other way round.

It will be an added recommendation to potential readers that more than half of the chapters have been written either by the editor himself or by other members of the staff of the Strangeways Laboratory. In an important sense, the appearance of this volume will make more easily available much of the research on tissue proteinases for which the Strangeways has become an acknowledged centre.

A. H. Gordon

A. H. Gordon is a member of the scientific staff at the National Institute for Medical Research, Mill Hill, London, UK.

Asymmetric reactions

Stereo-Differentiating Reactions: The Nature of Asymmetric Reaction. By Yoshiharu Izumi and Akira Tai. Pp. ix + 334. (Kodansha/Academic: Tokyo, New York and London, 1977.) \$29.50; £20.95.

FROM the introduction, it would seem that this book has two main aims: (1) to provide an introductory text with the basic physics and mathematics appropriate to asymmetric reactions; and (2) to present a new system of classification of asymmetric reactions developed by the authors and previously published in Japanese. One wonders what kind of reader the authors had in mind, since they have written a book which anyone unfamiliar with the field would have considerable difficulty in following and and which therefore cannot be regarded as an introductory text. A research worker interested in the mechanism of asymmetric reactions, on the other hand, will hardly want a research monograph to contain a chapter "Basic Principle of Optical Activity" or even one on experimental methods.

The key chapters are those in which the authors give their new nomenclature and classification. The authors' exposition is sometimes difficult to follow. They write: "A stereoselective reaction is defined as one in which one specific stereoisomer is produced to a greater extent than the other", but give as an example, the conversion of maleic and fumaric acids to maleic anhydride! They then go on to introduce terms like enantiozeroplane, enantiotopos, enantioface, or diastereotopos-differentiating reaction, and the

reader is bound to wonder if these terms are necessary. Are they really useful? Does their use clarify problems in reaction mechanisms?

The new classification with six reaction types could have some advantages when considering mechanistic problems. The chapters which discuss these in detail, and which form the bulk of the book are, however, disappointing. They contain a mass of information about organic reactions and about mechanisms proposed in the literature. The extensive discussion of the authors' own work on modified Raney nickel catalysts provides an interesting test case, and it must be said that nothing has been written which could not have been written as clearly or indeed more clearly without recourse to their terms.

One is left with the feeling that the authors have made a brave effort to think about problems which are conceptually notoriously difficult, and that their ideas are not without value. Their own exposition, however, is unconvincing and it would have been far better to have written a much shorter book with fewer examples to try and make their concepts clear.

The occasional absence of the definite article indicates that the translator was Japanese; on the whole, the translation is good, but there are quite a lot of misprints. The index is inadequate; for example, one could not discover from it that Grignard reactions are twice discussed, the only entry being a subheading under "enantioface-differentiating reaction".

T. L. V. Ulbricht

T. L. V. Ulbricht is Scientific Adviser (Special Duties) at the Agricultural Research Council, London, UK.

announcements

On the Move

T. J. Martin, Professor of Chemical Pathology, University of Sheffield, to Professor of Medicine, University of Melbourne, Repatriation General Hospital, Australia, from 1 October 1977.

N. H. Hunt, Department of Chemical Pathology, University of Sheffield, to Department of Experimental Pathology, John Curtin School of Medical Research, A.N.U., Australia.

Details of changes of department, sabbaticals, where leave will be taken and so on should be sent to On the Move; there is no charge for this service.

Appointments

Dr D. F. Hornig, President-emeritus of Brown University to Professor of Chemistry in Harvard Faculty of Public Health to direct development of a proposed University-wide undertaking, Interdisciplinary Programs in Health.

Mr L. R. Hanton, University of Otago, New Zealand, to a Rutherford Scholarship for three years from 1 October 1977 to work in the department of organic and inorganic chemistry, University of Cambridge.

Awards

Dr D. Schofield, chief of the Defence Research Establishment at Dartmouth, N.S. to deputy chief of laboratories, responsible for all Department of National Defence research establishments. Dr Schofield will be replaced by F. A. Fergusson, Deputy Chief in Ottawa.

Dr S. Weinberg, Higgins Professor of Physics at Harvard University and Senior Scientist at the Smithsonian Astrophysical Observatory, is the 1977 winner of the American Institute of Physics-United States Steel Foundation Science-Writing Award (\$1,500) for his book, 'The First Three Minutes', relating the theory of elementary particles to the problem of the very early moments of the Universe.

The British Council East European Exchange Visits

Cultural agreements with the Soviet Union, Czechoslovakia, Hungary, Romania and Bulgaria provide for short visits (usually 2 weeks) and medium term research visits (2-6 months) for British scientists. Scholarships are also available for periods of up to one academic year. For full

details and application form, contact Higher Education and Science Department, The British Council, 10 Spring Gardens, London SW1, UK.

Meetings

21-22 October, **International Symposium on Chromogenic Substrates**, London (Thrombosis Research Unit, Department of Surgery, Denmark Hill, London SE5, UK).

2-4 November, **Symposium on Advanced Ozone Technology**, Toronto (A. Netzer, Head, Physical Chemical Processes, Wastewater Technology Center, Canadian Center for Inland Water, PO Box 5050, Burlington, Ontario, Canada).

2-5 November, **Symposia on Perspectives in Biochemistry, and Isoenzymes**, Cordoba, Argentina (R. Caputto, Departamento Quimica Biologica, Facultad de Ciencias Quimicas, Universidad Nacional de Cordoba, Ciudad Universitaria, 5000-Cordoba, Argentina).

9 November, **Liquid Crystals**, London, UK (The Institute of Physics, 47 Belgrave Square, London SW1, UK).

9 November, **Symposium on Humidity Measurement**, London, UK (Sira Institute Ltd, South Hill, Chislehurst, Kent, UK).

Person to Person

Mathematician seeks family accommodation in Oxford, January to December 1978, or exchange house in Newcastle, N.S.W., Australia. Contact W. Brisley, Mathematics Department, University of Newcastle, N.S.W. 2308, Australia.

There will be no charge for this service. Send items (not more than 60 words) to Marcus Dobbs at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

10-12 November, **Open Conference on the Implications of Recombinant DNA Research**, Bloomington, Indiana (Professor R. P. Bareikis, The Poynter Center 410 North Park Street, Bloomington, Indiana 47401).

14-15 November, **New Developments in Immunoassays**, Düsseldorf (M. A. Andreopoulos, Conference Director, Robert S. First, Inc., Avenue Marnix 19A, Box 6, 1050 Brussels, Belgium) (also in Chicago, 5-6 December).

14-15 November, **Symposium on Mass Spectrometry and Combined Techniques in Medicine, Clinical Chemistry**

and Clinical Biochemistry, Tübingen (Medizinische Klinik, Universität Tübingen, Otfried-Müller-Strabe 10, 7400 Tübingen, GFR).

14-17 November, **International Symposium on the Pineal Organ**, Jerusalem (I. Nir, Faculty of Medicine, Hadassah Medical School, Jerusalem, Israel).

14-18 November, **The Pan American Conference on Forensic Applications of Anthropology, Dentistry, Medicine and Palaeopathology**, Mexico City (W. G. Eckert, Laboratory, St Francis Hospital, Wichita, Ks. 67214).

17-18 November, **Symposium on Nutritional Management of Genetic Disorders**, New York (The National Foundation-March of Dimes, 622 Third Avenue, New York, N.Y. 10017).

21-26 November, **Fifth International Conference on Global Impacts of Applied Microbiology**, Bangkok (Chairman, GIAM V, National Organising Committee, Mahidol University, GPO Box 4-130, Bangkok, Thailand).

22-23 November, **Symposium on Photography in the Laboratory**, London (The Secretary, Scientific Symposia Ltd, 42-43 Gerrard Street, London W1, UK).

Facing up to demography

THE United States is gradually, if painfully, coming to grips with the problems of discrimination within its society. Most liberal-minded people have gone along with much that has been done in the past fifteen years, even when initial efforts to reduce discrimination have not been sophisticated or quick-footed enough to avoid charges of reverse discrimination, as in the case of Allan Bakke, a white student with good grades excluded from the medical school of the University of California at Davis. Racial minorities, women, the handicapped—these are causes with which very few would disagree. But scientists, in particular, are having very mixed feelings about the plight of those most recently claimed to be discriminated against—the elderly.

A bill that has just passed through the US House of Representatives with negligible opposition would prohibit mandatory retirement in private employment before the age of 70, and would prohibit mandatory retirement in the federal sector at any age (with exceptions such as the police and firefighters). At present private employers may retire their staff at 65, the federal government at 70. These moves came about for two reasons, both connected with demographic changes which are progressively peopling the United States with older citizens (23 million are 65 or over at present, and 31 million are expected to be so by the end of the century). First, the burden of social security payments is going up, yet the numbers of new workers is going down as the birthrate declines, so there are good actuarial reasons for wishing to postpone retirement. Second, the elderly are rapidly becoming a potent political force, of which politicians are becoming increasingly aware.

The bind for scientists is this: that deep concern was already being expressed before the retirement bill ever surfaced over the way that university faculty employment was moving towards a crisis. In 1979 there will be 4.3 million American eighteen-year-olds, 60% more than in 1960. The course of university expansion in the 1960s ensured that these young people would be well catered for. But after 1979, the numbers will steadily decline until in 1990 there will be fewer than 3.5 million in this age bracket. Many universities will presumably have to go out of business and elsewhere faculty will have to be trimmed. Things look particu-

larly bad in the physical sciences; an NSF projection puts the number of faculty positions in 1985 at 25% less than the number in 1972. Nor can this attrition be taken care of solely by retirement. Vigorous recruitment over the past thirty years has ensured that there is a predominance of young to middle-aged faculty members at present. So the prospects for the post-doctoral worker looking to get a toehold on the academic ladder already seemed bleaker than ever before. Nor should the position of the scientist working for the government be reckoned to be very different. Federal agencies have often followed very similar employment policies to those of the universities.

The new retirement legislation would obviously compound these problems very seriously, so it is small wonder that academic employers have been lobbying hard for exemption this past week. They have so far met with some success in that the Senate Human Resources Committee, in endorsing the bill (which now goes to the Senate), has excluded universities from its provisions. But no one seems yet to have spoken up for the federal government laboratories, where scientists will, presumably, be able to go on working to any age they choose.

Even if universities do emerge from the legislation relatively unscathed, there will still remain the urgent question of diminishing job prospects for the young. Richard Atkinson, Director of NSF, has recently made some fairly radical proposals (*Chronicle of Higher Education*, 28 March). These are that the government should facilitate more mid-career shifts for those who wish to depart early; that research institutes should be established close to or within universities to which senior academics could move, devoting more of their time to research and passing their teaching load on to newly employed junior faculty; and that industry should take greater advantage of the basic-research skills of senior academic scientists in some form of joint venture.

All of these proposals are doubtless open to many and varied criticism, but we simply cannot afford the luxury of a lengthy and hair-splitting debate on the subject. Action is needed in the very near future, otherwise demography will be upon us and we will be responding to the crisis in an arbitrary way. That would lead to an even worse form of discrimination. □

The long journey into the end of the artificial night

Sargun A. Tont, staff research associate at Scripps Institution of Oceanography, University of California at San Diego, offers a view on the study of solar eclipses

ALTHOUGH the occurrence of a solar eclipse is one of the most precisely predicted phenomena in the entire solar system, the chances of its coinciding with clear skies are about as good as Mr Buckley's inviting Mr Vidal for a transatlantic cruise on his yacht, or Bobby Fischer's opening with a queen's pawn.

Although unfriendly weather is an important obstacle for eclipse lovers, it is far away from being the only one. Getting to the path of an eclipse usually turns out to be a problem that itself exercises a good bit of human ingenuity. For the past of a total solar eclipse seldom favours highly populated regions. There is no reason that it should, of course, yet the number of eclipse paths which run toward far-away places almost appears designed to test the limits of human curiosity. Not surprisingly, then, the traditional vehicles for eclipse expeditions have been mules, donkeys, camels, sledges drawn by Alaskan huskies, trains and, of late years, even chartered jets. In 1972, a novelty was added: a huge, luxurious ocean liner, the *T.S.S. Olympia*, carried 800 eclipse freaks 900 miles out into the cold Atlantic.

The following paragraph from the *New York Times* of 30 July 1972 explains my presence on that ship of fools, as it appeared to me at the start:

A team from the Scripps Institute [*sic*] of Oceanography in La Jolla, California, would conduct an eclipse experiment possible only at sea; they would lower a 300-pound echo chamber over the *Olympia's* bow to determine whether the layer of microscopic ocean animals called plankton rises at night merely because it gets dark or because of an internal biological clock that would not be triggered by the extraordinary, sudden darkness of the eclipse.

In short, an eclipse provides a sort of artificial night for testing this unique hypothesis.

The ships may be more luxurious and larger, but the age-old problem of not being able to avoid undesirable situations seems to remain the same. The problem in my case was 350 freelance writers who were looking for interesting angles, which primarily meant interviewing me, the expedition leader, and my colleague and friend Dr Gerald Wick. However, as the big day approached, we were pretty much left alone, and I was able to take a closer look at my fellow passengers. They were a most interesting bunch. Astronaut Scott Carpenter, along with several members of New York high society, were there. So were secretaries, nurses, and several professional astronomers.

People have responded to solar eclipses in a variety of ways. One king, Louis of Bavaria, was frightened to death by it. A solar eclipse stopped a battle between the Lydians and the Medes, and, as late as 1948, the Korean national elections were postponed, again because of an eclipse. American Indians have described eclipse as "the sun being very sick and going to bed"; and India's Indians have interpreted them as the sun being devoured by evil spirits. Our fellow passengers might have lost some of the fear which beset their early ancestors, but definitely not their reverence and enthusiasm. When I asked several of them how it felt to witness an eclipse, the answers were invariably the same: "There is nothing like it". Like what? Few people seemed to know, or were prepared to say. Yet Leif Robinson, the associate editor of *Sky and Telescope* and a fellow passenger

on board the *Olympia*, probably summed up best what it is about eclipses that forces us to follow them wherever they take us: "Every solar eclipse unfolds in a predictable way, only the details changing. It is the manner in which these subtleties of colour, brightness, and form are blended that gives each eclipse a flavour as distinct as vintage wine". Conrad would have liked that.

It did not take me long to discard my idea that the passengers were on this cruise to have a good time, in addition to watching the eclipse. It was the eclipse and the eclipse alone that they were after, and many, I am sure, would have swum the distance if that were the only transportation possible. Nevertheless, the entrepreneur of the cruise, Phil Siegler, a social scientist from New York, had also insured a full house by offering something called 'Science at Sea'. Courses ranging from astronomy to bird-watching were taught by astronomers, atmospheric scientists, Scott Carpenter and Leif Robinson.

Nor, as it turned out, was our group the only one mixing pleasure with business. Milner Schaefer, the inventor of cloud seeding and a most charming man, was geared to record cosmic rays; and Dr Williams, of Yale University, passed out photocopied notices inviting all interested passengers to share their eclipse-related dreams with him as a part of his research project¹. However, the most important scientist on board was the meteorologist whose primary function was to guide the ship to the most favourable (that is, cloud-free) location. Outfitted in a Scottish tweed jacket and impeccably shiny shoes, he entered into Ahab-like trances which never failed to command our closest attention, and his least utterance about the weather was speedily relayed to the farthest corner of the vessel.

Then it happened. It wasn't what I expected. What surprised and fascinated me was not the sudden darkness which swooped down on us with the grace of a hammer-head entering a South-Sea lagoon, but the grasshopperesque chatter of cameras, all 799 of them. I suddenly realised that I might be the only one who was watching it—the rest were busy recording it for posterity, be it for a lecture demonstration for an undergraduate astronomy class at Harvard, or for a slide show especially prepared for a maiden aunt and her boyfriend in Galesburg, Missouri. What a pity! Thanks to the camera, most people became the lovers of an illusion of reality, rather than of the reality itself.

It is that time again and the faithful are getting ready to watch, on 12 October, the total solar eclipse which, according to reports, will be best viewed off the coast of central America (13° 42'N 123° 07'W). In order to accommodate the large number of applicants, Sitmar Lines is offering two ocean liners, along with such luminaries as Margaret Mead and Isaac Asimov. If you happen to be in the neighbourhood, take a look at it. It is some sight.

As for our experiment², in the finest scientific tradition, the results were rather ambiguous. Even though some of the organisms responded to the eclipse by migrating vertically, some did not. One of the results was totally unexpected: increased bioluminescent activity during totality. One can offer several hypotheses to explain this phenomenon, but I am sure, to the eclipse lover, this was nothing more than the little bugs celebrating the joyous occasion.

¹ For the various scientific projects conducted during solar eclipses, see *Solar Eclipse Bulletin 1-4* (National Science Foundation, Washington, D.C.; 1973).

² For the results of our experiment, see *Deep-Sea Research* 20, 769-771; 1973.

Two decades of Soviet space

Vera Rich looks at the Soviet space programme, twenty years old this week

ON 4 October 1957 the first artificial satellite, later to be known as *Sputnik 1*, was launched as part of the Soviet contribution to the International Geophysical Year. From the Soviet point of view, the date fell auspiciously close to the 40th anniversary of the October Revolution, and also in the centenary year of the birth of Konstantin Eduardovich Tsiolkovskii, 'the father of cosmonautics'. During the subsequent decade the Soviet space programme notched up an impressive number of 'firsts'—first animal in space, first lunar impact, first circum-lunar probe, first man in space, first (and to date only) woman in space, first interplanetary probe, first automatic docking and separation. The USSR could even claim the first 'space baby', Elena, the daughter of cosmonauts Tereshkova and Nikolaev, whose healthy arrival did much to disperse alarmist fears of the genetic hazards of space flight.

It was not until the late 1960s that the unbroken run of Soviet 'firsts' slowed down. Like the Apollo 8 accident in the USA, the tragic death on 24 April 1967 of Vladimir Komarov, whose re-entry parachutes failed to open properly, put an end to the euphoria. The death a month before of Yuri Gagarin in a flying accident not only deprived the Soviet Union of its greatest living hero, but also appears to have caused a major change in policy. During her post-mission world tour, Tereshkova had told a press conference in Cuba that the Soviet moon team had already been picked and that Gagarin was to lead it. Since his death, no mention has been made of a manned lunar mission in the foreseeable future and, with the success of the US Apollo missions, the Soviet planners have preferred to stress the considerable saving (up to 50%) effected by using unmanned rather than manned lunar probes.

This stress on saving is not simply a face-saving excuse. The actual cost of the Soviet space programme is a closely guarded secret, but from the very beginning there was a strong body of feeling that whatever the cost might be, it was too high. A whole series of black jokes circulated, based on the resemblance of the word for meat (*myaso*) and the archaic name for the moon (*mesyats*), suggesting that the shortages of the one were not unconnected with the rockets to the other. By 1960, *Komsomolskaya Pravda* had to launch a special campaign to quash

such criticism. But public opinion had made its point; the comrade-in-the street was not prepared to accept pie-in-the-sky as a substitute for consumer goods on earth. Gradually it became standard practice to announce all space-missions as being "in the interests of the national economy"—a phrase which seems somewhat hard to justify (except in terms of serendipity) when applied to a Venus or Mars probe.

Terrestrial applications

A considerable proportion of Soviet launches do, of course, have terrestrial applications. The *Meteor* meteorological satellites, and the *Molniya* communications satellites have proved invaluable in the opening up of Siberia, not the least of the advantages of *Molniya* being that it provides the solace of TV for workers on remote construction sites. Visual and infrared photography, from manned and unmanned satellites, has found a wide range of applications from oil-prospecting to fish-spotting. The *Kosmos* series of satellites, initiated in 1962 and now approaching the 1,000 mark, covers a number of such applications. The vagueness of the series title makes it an ideal cloak for any purpose the planners may wish to conceal. In the early days unsuccessful lunar or interplanetary probes were assigned a *Kosmos* number, while *Kosmos 47* was probably an unmanned trial run for the manned *Voskhod 1*, which followed a week later.

Initially one of the basic missions of the *Kosmos* programme was stated to be the monitoring of high-altitude nuclear explosions. *Kosmos 5*, in particular, measured the decay of high-altitude radiation following the American 'Starfish' nuclear test of 9 July 1962. Happily the 1963 atmospheric test ban treaty rendered this part of the programme obsolete. There is little doubt, however, that the *Kosmos* series is not without its military applications; and the term *Kosmos* has also covered various 'occasional' experiments, including automatic docking, and tests on biological specimens.

With the abandonment of any immediate plans for a manned moon mission, the Soviet manned space programme became centred on the concept of orbital space stations—the approach which had been favoured by Tsiolkovskii himself. The first such station, *Salyut 1*, was launched in 1971. Although the success of the mission was overshadowed by the death of the second-shift crew during re-entry, the

Where it all began: Sputnik 1

Where the USSR is now: Soyuz 24 about to take off

series continues, and this week's anniversary is marked by the launch of *Salyut 6*, as well as by the publication by the Crimean Astrophysical Observatory of a 'catalogue' of solar radiation of various wavelengths and a detailed spatial distribution of the temperature of solar flares, based on films taken aboard *Salyut 4*.

According to Academician Georgii I. Petrov, the *Salyut* programme is a three-fold one—astrophysical observations, surveying earth resources, and physical experiments associated with weightlessness. Already a number of interesting results have been reported on crystal growth and the cooling of liquid metals in weightlessness; in a recent *Pravda* interview Petrov suggested also that a space station would be a suitable base for producing specimens of ultra-high purity.

He further suggested that such space stations could well provide a base for a long-term moon expedition. He envisaged a lunar-orbital station with a crew aboard; they would send down automatic probes and sampling devices to the surface of the moon, to make observations or bring back specimens as required. "I can see no reason", Petrov remarked, "that would require man to make a long-term stay on the

moon". He then proceeded, not surprisingly, to rule out any possibility of a manned Mars mission, largely on the grounds that the biological effect of long-term weightlessness is still unknown. If weightlessness really presents such a danger, it seems a little remarkable that a Soviet manned 'lunar' mission would preferably be kept in orbit rather than allowed to benefit from the reduced but at least perceptible gravity of the moon.

No further

For the moment, it would appear, Soviet man will venture no further than a circumterrestrial orbit. Not surprisingly, the "most interesting" future experiments which Petrov outlines will all be carried out by unmanned probes—the collection of highly rarefied 'undamaged primary meteorite material', and the recovery of solid material from interplanetary space. Other exciting projects for robot probes include flights over the poles of the sun, and a deep-level descent into the atmosphere of Jupiter. And, said Petrov, the only sure way to solve the age-old problem of whether there is life on Mars is the automatic recovery of a soil specimen from the planet. It is here, incidentally, that Soviet expertise gained during the automatic moon programme will pay off. The specimens of lunar soil recovered by the *Luna* probes were far smaller than those brought back by the Apollo crews, a fact which the US media were not slow to note and which the Soviet publicists played down by stressing the technological prowess behind automatic sampling. For Mars, however, automatic sampling will probably antedate any manned mission by a number of years, while in the case of Venus, automatic sampling would appear essential. Similarly, a roving vehicle of the *Lunokhod* type could easily be redesigned as a *Marsokhod*, with only minor modifications to the Martian environment.

To launch such missions, there are, according to Petrov, "lively discussions" about the possibility of a "reusable" launch craft similar, presumably, to the US Space Shuttle but possessing, if necessary, two returnable launch stages.

International cooperation

One aspect of the space programme was not mentioned by Petrov—international cooperation. That is the responsibility of his namesake, Academician Boris N. Petrov, the head of the *Interkosmos* programme. *Interkosmos* itself is the space research organisation of the Comecon block, launching the astrophysical *Interkosmos* satellites (17 to date) and the *Vertikal* high-altitude rockets. However, the Soviet Union also has programmes of space cooperation with other countries,

1967: Kosmos 186 and Kosmos 188 approach for automatic docking

Training in capsule recovery in water: normal Soviet style is over land

notably France, India, Sweden, and the USA. The type of cooperation varies from country to country.

To date the Franco-Soviet programme has been the broadest based, and has included geodesy, aurora borealis/australis, and interplanetary particle flux experiments, as well as laser ranging to the moon, using French reflectors on *Lunokhods* 1 and 2. A Swedish experiment on ultraviolet solar radiation was carried by *Interkosmos* 16 under an agreement with the Soviet Academy of Sciences, and a new cooperation agreement signed last month will provide for Swedish magnetosphere-plasma experiments to be carried by Soviet high-apogee satellites.

The most significant cooperation agreement of the whole 20 years, how-

ever, was that between the USA and the Soviet Union, which culminated in the Apollo-Soyuz link-up of July 1975. The space age began in an atmosphere of mutual doubt between the superpowers—the Soviet triumphantly, the USA fearfully assessing the propaganda advantage of *Sputnik* 1. It took several years for even so innocuous a matter as the exchange of high-altitude meteorological photographs to become a matter of practical politics. The political and psychological implications of space-flight are too large a subject to be dismissed in a paragraph; nevertheless it may well be that *détente* on the one hand, and the growing concern with conservation and ecology on the other, are themselves as much a product of the space age as an Apollo capsule or a Venus descent craft. □

CANADA

Digesting the food problem

David Spurgeon writes from Ottawa on the impact of a symposium held in August to consider how Canada could best contribute in the future to the alleviation of world food shortages

A SYMPOSIUM on the theme "Canada and World Food" has had the paradoxical effect of bringing to the fore some deep-seated concerns about the state of Canadian agriculture itself. Sponsored by the Royal Society of Canada and the Agricultural Institute of Canada, and featuring some leading figures of Canadian and US agriculture and foreign aid programmes, the meeting also brought into question some of the country's official food aid policies.

Some consensus was reached at the meeting. There seemed to be general agreement that the world food supply was precarious, but that world agriculture was capable of producing enough food to meet demand in the near term. There also appeared to be general agreement with the idea that the world's food security was a political and not an economic or scientific question. Too little emphasis was seen to be placed on agriculture by developing countries.

But the symposium also brought out wide differences of opinion on the effects of food aid and its consequent value to developing nations. On the Canadian position, for example, Gordon A. MacEachern, president of the Agricultural Economics Research Council of Canada, had alarming things to say. He maintained there had been "a serious deterioration in Canada's agriculture-food industry output, trade, productivity performance, and a serious decline in our relative contribution to world food, compared to earlier periods and the performance of other net food exporters, most notably the United States".

Though others pointed out that Canada currently is the world's second largest supplier of food aid, MacEachern said there seemed

little benefit in addressing the relatively attractive world food demand prospects, or the economic potential for Canada expanding its agriculture-food capacity to play a greater role in world food supplies, when its cost-price structure says it can't compete. Pervasive voices from almost all segments of Canada's agriculture and food industries are echoing these sentiments, as are senior agricultural officials in Canada, suggesting that what is presently at stake is the very survival of our agriculture-food industries.

Canada continues to enjoy a favourable trade balance in food, as it always has. But over the past 20 years the country's food and feed exports have not kept pace with the growth of either the Canadian or the world economy or the growth in world food and feed trade. In the past five years, Canada has maintained a net export position for only a few commodities such as grain and oilseeds, and in these output and export performance have remained more or less static.

One reason for this, said MacEachern, is the steady growth in Canada's food imports, two-thirds of which are similar to or the same as foods that can be grown in Canada. Other reasons included the artificial support of the Canadian dollar by the federal government, the high level of wage rates in the industry in Canada, and an effective level of protection of 20-40% for manufacturing industry, which further raised agricultural costs.

Len Shebeski, dean of the University of Manitoba's faculty of agriculture, quoted a pessimistic comment made in June by Dr Fred Bentley of the University of Alberta's soil science department, who is chairman of the board of

trustees of the International Centre for Research in the Semi-arid Tropics (ICRISAT) in India. Without a massive and well-coordinated effort to meet the needs of agriculture, he had said, Canada could become a food deficit nation before the end of this century. Shebeski disputed this. He believed that Canada's agricultural potential was even greater than the 65 and even 100% increase over present production others had suggested. He based his prediction on the possibility of doubling the land area devoted to agriculture and a 60% increase in yield per acre through improved management. Agricultural lands in Canada had the potential—with present technology—for "more than three times present production of field crops and more than ten times the present ruminant livestock production". And these estimates could be revised upwards "if adequate moisture supplies in the more arid regions of western Canada could be assured."

Shebeski wondered, however, whether Canada ought to reach such production figures. "Because Canada, territorially, is the second largest country in the world, there has developed a popular belief—often voiced—that it is the bread basket of the world," he said.

Indian wheat harvest: but how to assure supplies?

MacEachern acknowledged that

Those of us involved in agriculture know that this is a myth. An examination of a world map depicting the agriculture lands of the world shows that Canada's component of the world's present 3.6 billion acres of crop land is approximately 5% . . . Canada's strategic position in the current world food situation does not arise from a high tonnage of food outputs, but rather from the large proportion of her total production available for off-shore consumption.

This production, he intimated, should not be relied upon freely by developing countries to fill their food shortages. The costs of claiming the 20 million hectares of potentially arable land of low fertility would be enormous. Crops produced would be modest in quantity and marginal or submarginal in profitability. The food produced would be thousands of miles from where it would be needed.

As an alternative, Shebeski proposed that the Canadian government, through the International Development Research Centre (IDRC) or the Canadian International Development Agency, make available to developing countries the money it would cost to bring large areas of potential Canadian land into food production. This money could then be used to bring into production land areas with the agricultural potential of the Indus-Ganges-Brahmaputra plain of North India, or parts of Brazil, where experiments have shown production possibilities of more than 70 bushels per acre. He had struck on a note that was echoed in much of the conference: investments in food production to meet shortages in developing countries should be made in those countries rather than in developed ones.

David Hopper, president of the IDRC, said food assistance should not be denied in cases of genuine emergency or hardship. But imports had in some cases in the past held domestic farm prices below levels that would have prevailed in the recipient countries had the imports not been available, and this had destroyed the incentives to generate local increases in food production. Where the food aid was essentially free, its sale within the country by the recipient government had directly augmented national treasury resources, reducing the need to tax more heavily or to encourage larger savings for domestic investment programmes. That blunted incentives for local development, and removed any urgency to look further into measures to promote the more rapid development of indigenous farming.

Fred Bentley proposed that, as a minimum, every food-deficient less-developed country should be required to increase the budget for agriculture by an amount at least equal to the value of food aid received, without any diminution in the percentage of the

national budget already being allocated to the agricultural sector. Alternatively, recipients could add the funds to their population control programmes. But T. K. Warley, of the School of Agricultural Economics and Extension Education at the University of Guelph, Ontario, defended food aid, saying it had served many purposes beyond providing increased food supplies to hungry people in poor countries, including the general transfer of resources to developing countries, support of the balance of payments and thus maintenance of high rates of economic growth, and promotion of political stability and allegiances. Food aid, he said, should be used to accelerate agricultural and rural development, alleviate hunger in specific target groups, and help build minimum stocks of basic foodstuffs.

Frank Shefrin, director of the Canada Department of Agriculture's international liaison service, summed up the magnitude of the world problem. He said that it was not enough to increase the production of food. There had to be increases in food production in the poorer countries and by the small farmers, so that imports of food would not exceed their means of paying. The food had to be produced where it was needed and get to those who need it. Just to stay at the present per capita food production, developing countries could require an annual investment in agriculture of about \$20 billion, of which 60-70% would have to come from the countries themselves unless there was a substantial increase in capital assistance.

Findings of the latest report of the International Food Policy Research Institute (IFPRI) in Washington were also revealed. Projecting food shortfalls of some 82 developing countries (containing roughly half the earth's population) by comparing prospective food production if performance continues in the next 15 years as it has in the past 15, IFPRI has come up with the following forecasts:

- A total food grain deficit among those countries with less than \$300 GNP per capita in 1973 of 70-85 million tons by 1990 (12 million tons in 1975).
- A need for some 35 million metric tons over and above the projected production in 1990 just to provide for population increases in these countries (maintaining per capita consumption at 1975 levels).
- Potential shortfalls by 1990 among all developing countries included in the study of 120-145 million tons, a figure which approaches the total volume of world grain trade in recent years.
- A potential shortfall of 21-25 million tons by 1990 in India, which has almost half the people in low-income

Onloading in Canada

Offloading in India

food deficit countries. To meet this, an increase in production of $3\frac{1}{2}\%$ a year would be required, compared to the historical $2\frac{1}{2}\%$.

- Deficits of 6-8 million tons each for Bangladesh and Indonesia. For Bangladesh, production would need to increase almost $4\frac{1}{2}\%$ a year compared to a historical rate of $1\frac{1}{2}\%$. For Indonesia, the rate should be $4\frac{1}{2}\%$ instead of the historical 3%.
- A deficit of 18-21 million tons facing Nigeria, which would require $5\frac{1}{2}\%$ increase a year (historic rate $\frac{1}{2}\%$).
- An increase to $3\frac{1}{2}$ -4% required in Sahel countries to avoid a shortage of $3\frac{1}{2}$ million tons (historic rate $-\frac{1}{2}\%$).
- To meet nutritional needs, most low-income food-deficit countries need an additional $\frac{1}{2}$ -1% growth rate over and above those necessary to meet market demand. □

USA

Department store

David Davies reports from Washington on the new US Department of Energy

THE Department of Energy, the twelfth Cabinet agency of the United States, comes into being on 1 October. Proposed by President Carter on 1 March of this year, the department will be headed by Secretary James Schlesinger. It will have almost 20,000 employees and a first-year budget of \$10,400 million. An amalgam of several agencies, most notably the Energy Research and Development Administration (ERDA) and the Federal Energy Agency, the new department's structure is a little unusual in that it is divided along functional lines rather than technological lines. Thus technologies will move through different parts of the department as they progress from basic research through development and into commercial implementation.

Responsibility for basic research will lie, in large measure, in the Office of Energy Research, which will manage basic science programmes both within the department's own laboratories and in the universities. The Director of this office will be Professor John Deutch, a physical chemist from the Massachusetts Institute of Technology. Deutch, 39, is no stranger to the Washington scene. In the 1960s he worked as a systems analyst in the Department of Defense, and consulted for the Bureau of the Budget. He has been a part-time member of the Defense Science Board, most recently as its Vice-Chairman. But he declares, indeed promises, that in several years time he will be back doing chemistry.

In the meantime he will play four major roles. He will provide Schlesinger with technical advice on basic science issues. He will co-ordinate

all the department's basic research, some of which will obviously be done outside the immediate orbit of his office. He will be responsible for the well-being of all the department's 144 laboratories (excluding the weapons laboratories). And he will be responsible for the financial support of basic research.

A very substantial fraction of the basic research money at present goes to high energy and nuclear physics, and clearly the future of this research is not too closely tied to immediate questions of energy policy. But in fiscal year 1977, \$125 million was spent in basic energy research, divided roughly 7:3 between governmental laboratory and university recipients. There is little doubt that this sum will rise sharply in the next few years; already federal financial obligations to energy R&D as a whole in fiscal year 1978 are seen as rising by at least 10% in real terms over the 1977 figure.

The department has an Under Secretary and six Assistant Secretaries on the technical side. Subject to confirmation, the Under Secretary, who will oversee all the programmes but have a special brief for energy conservation, is Dale Myers, at present a Vice-President of Rockwell International. Apart from basic research the Assistant Secretaries also cover energy technology; resource applications, with responsibility for the commercial introduction of new technology; conservation and solar applications, a contact point for individual inventors and small businesses; environment, with responsibility for ensuring that programmes comply with environmental health and safety regulations and with the authority to conduct related research; and defence programmes, directing nuclear weapons research and investigations into laser fusion. □

Research director: John Deutch

DNA bill delay

RECENT moves on Capitol Hill have created further confusion in the already contorted story of the various pieces of pending legislation to control recombinant DNA research in the United States. In the House of Representatives, the bill drafted by Rep. Paul Rogers' Health subcommittee was scheduled for consideration by the Commerce Committee last week and was not expected to run into much trouble. Commerce chairman Harley Staggers postponed consideration of the bill, however, and suggested that important amendments might be required. Further amendments have been proposed by other committee members. The chances that the bill will be approved by the committee and reach the floor of the House before the end of the legislative session have now diminished almost to zero.

In the Senate the situation is more confusing. The Kennedy bill which was already running into trouble with Senators concerned about its bureaucratic provisions has been removed from the legislative calendar. Senator Kennedy now proposes to set up a Study Commission composed of interested members of lay and scientific organisations to consider the best form of legislation. As a stopgap, a simple measure to give the NIH guidelines the force of law would be enacted. This would apparently contain no enforcement provisions but would apply to industry as well as government-financed research. The position of the bill recently drafted by Senator Gaylord Nelson, which is similar in many respects to the House bill (see *Nature*, 1 September) is not clear, although it does not now appear to be gathering sufficient support for passage this session.

In addition Senator Adlai Stevenson III, as chairman of the Subcommittee on Science, Technology and Space of the Senate Commerce Committee, has announced hearings on the effect of the proposed legislation; at the same time he expressed strong misgivings about the pending bills and their effect on basic research and freedom of scientific enquiry.

All these moves owe something to the lobbying efforts of some scientists and scientific societies, together with statements on the relative risks and benefits of recombinant DNA research from a number of scientific meetings over the summer. More battles are in store before legislation finally emerges.

Sandy Grimwade

IN BRIEF

UK sweetener review

The UK Food Additives and Contaminants Committee is to conduct a full review of the regulations controlling the use of artificial sweeteners in food. The committee, which falls under the aegis of four governmental departments, will thus extend its present studies of saccharin and of Aspartame; it has published two reports on cyclamates in the past.

Waste now, power later

A three-member panel of the White House Council of Environmental Quality has, according to the *New York Times*, reported that an expansion of nuclear power in the United States should be made conditional upon a demonstrably safe method of containing nuclear waste. The verdict is seen less as a counter to President

Carter's energy plan than as an attempt to encourage work on waste disposal.

IAEA reprocessing view

Though it was generally accepted that the number of nuclear fuel reprocessing plants should be kept to a minimum, to prohibit them would probably lead to a result opposite of that intended, according to Dr Sigvard Eklund, the Director General of the International Atomic Energy Agency (IAEA). He was speaking at the IAEA General Conference's 21st Regular Session in Vienna last week. Dr Eklund, who was appointed to his fifth consecutive term as director general, was also critical of those who wanted to eliminate the nuclear option.

Accelerator approval

Approval has come for the construction of Brookhaven National Laboratory's 200 GeV superconducting

intersecting storage ring accelerator Isabelle. A joint US House-Senate committee last week authorised expenditures totalling nearly \$200 million. The device will enable protons to be fired at each other with centre of mass energies well in excess of those available elsewhere, providing detail on how and if the weak and electromagnetic interactions are unified.

HSC report

A broad-ranging 51-page report from the UK Health and Safety Commission, published this week, details the work of the Commission and its Executive between their establishment in October 1974 and January 1975 respectively and March last year. The Commission emphasises that legislation can play only a part in achieving the objectives of the Health and Safety at Work Act, and indicates in its discussion of future strategy what more can be done.

THE field of molecular evolution deals largely with comparisons of the sequences of 'informational macromolecules'—DNA, RNA and proteins. The first sequences that were available were of proteins: cytochromes *c* and haemoglobins, from different animals. The story is now familiar: the number and location of differences in corresponding amino acids were roughly proportional to the taxonomic separation of two species. For example, human and rhesus monkey haemoglobins differ in 12 locations; human and horse haemoglobins in 42; rhesus monkey and horse in 43. The differences between human and horse are not all in the same places, or of the same kind, as the differences between monkey and horse, thus showing that the three species have followed separate evolutionary pathways. These findings expanded and accumulated for various families of proteins, and were extended into comparisons between insects, green plants, yeasts and moulds. Various authors constructed large 'phylogenetic trees' based on such findings. It became evident that a 'molecular evolutionary clock', ticking away through the aeons, left its imprint in terms of divergence between sequences. The clock did not always run at the same rate, but, in the main, the divergences roughly corresponded to the passage of time as judged by other criteria, such as the fossil record.

But wait! The differences between proteins were merely the expression of changes in the base sequences of

'codes'. Quite often, two to four DNA molecules as reflected by the genetic code. And the genetic code, or amino acid code, is ambiguous in certain respects, because 18 of the 20 amino acids have from two to six

Molecular evolution

THOMAS H. JUKES

codes for the same amino acid differ only in the third base of the nucleic acid codon that specifies the amino acid. So a change of one amino acid, as measured in a protein, could reflect more than one change in a gene. Various 'educated guesses' were proposed to calculate the actual numbers of such unknown changes.

The discovery of procedures for

rapidly determining the sequences of long segments of DNA molecules is going to revise all this. One such method came from Sanger's group at Cambridge, and, more recently, the field has been galvanised by a chemical procedure devised by Maxam and Gilbert at Harvard. Such sequences can be matched against a protein sequence, even a partial one, and the exact code for each amino acid can be 'read off'. Furthermore, comparisons of DNA sequences obtained from homologous regions in related organisms tell precisely which nucleotides have undergone change during the period of evolutionary separation. There are preliminary indications that the synonymous 'third bases' of codons may undergo such changes more frequently than the first two bases, which specify amino acids.

New techniques, such as automated Edman degradation, are improving the accuracy of measuring amino acid sequences in proteins. A sequence between the 23rd and 30th residues in cytochrome *c* of *Neurospora crassa*, previously listed as -Gly-Glu-Gly-Gly-Asn-Leu-Thr-Gln- was found to be -Thr-Leu-Glu-Glu-Gly-Gly-Asn-. This was a bit of a shocker, and it called for some revision of evolutionary comparisons, but it is probably an extreme case. Other re-evaluations, and an expansion of ideas on evolution, will stem from forthcoming studies of DNA molecules. These studies should shed new light on the question of 'neutral' or 'near-neutral' evolutionary changes that occur in genes.

Molecular basis of plant tumour induction

from James A. Lippincott

THE long sought tumour-inducing principle (TIP) produced by the bacterium *Agrobacterium tumefaciens* and responsible for the transformation of normal plant cells to tumour cells (crown gall) seems now to be largely identified. This bacterium is known to cause transformation in a wide variety of plants when it infects wounded areas. Unlike cells of the nitrogen-fixing nodules induced by rhizobia, however, these tumour cells do not contain bacteria, and the bacterium needs to be present for only hours to a few days to induce tumours which will continue to proliferate in their absence. This growth autonomy is maintained in tissue culture where the tumours do not require hormones for growth, as do most normal tissues. The tumours also continue their characteristic growth when the bacteria-free cultures are grafted on normal plants. This evidence suggested that a TIP was produced by the bacterium and could alter the growth and developmental potential of plant cells in an essentially permanent fashion.

A major break in the problem came with the demonstration that tumorigenic strains of *Agrobacterium* carried a large ($>110 \times 10^6$ daltons) circular extrachromosomal DNA element or plasmid, whereas several non-tumorigenic strains did not (Zaenen *et al. J. molec. Biol.* **86**, 109; 1974). One strain of *Agrobacterium* readily loses virulence when grown at 37 °C (Hamilton & Fall *Experientia* **27**, 229; 1971) and this was shown to be accompanied by plasmid loss (Van Larebeke *et al. Nature* **255**, 742; 1974; Watson *et al. J. Bact.* **123**, 255; 1975). Genetically marked non-virulent strains of *Agrobacterium* had been found by Kerr (*Nature* **223**, 1175; 1969; *Physiol. Plant Pathol.* **1**, 241; 1971) to

acquire virulence after several weeks when co-inoculated on plant hosts along with virulent bacteria. This gain of virulence was also shown to depend on the plasmid and results from the transfer of a plasmid *in planta* from the virulent to the non-virulent strain (Watson *et al. op. cit.*, Van Larebeke *et al. Nature* **255**, 742; 1975). The necessity of the plasmid for tumorigenicity was thus firmly established. More conventional methods of plasmid transfer have since been developed and results from these tests fully support the initial findings (Levin *et al. J. Bact.* **127**, 1331; 1976; Chilton *et al. Genetics* **83**, 609; 1976; Kerr *et al. Nature* **265**, 560; 1977; Genetello *et al. Nature* **265**, 561; 1977).

Direct evidence that the *Agrobacterium* plasmid is the TIP or at least a major essential element of this concept has now been obtained. Chilton *et al. (Cell* **11**, 263; 1977) have isolated DNA from normal and crown gall tumour tissue cultures and hybridised it with different restriction nuclease fragments of the *Agrobacterium* plasmid. Most plasmid fragments do not hybridise with either normal or tumour DNA. Two plasmid pieces, however, hybridise with tumour DNA but not normal DNA, indicating that the tumour cells have acquired plasmid DNA sequences as a consequence of the transformation process. About 20 copies of a $3.7-6 \times 10^6$ dalton plasmid segment are estimated to be present in each tumour cell, sufficient information to code for about 10 different proteins.

Further support for these results, obtained by hybridising RNA isolated from tumour cells and normal cells with nuclease fragments of the plasmid, is reported by Drummond *et al.* in this issue of *Nature* (page 535). RNA transcripts of one plasmid segment are found in the tumours but not in normal tissues and this segment is the same as one detected by DNA-DNA

hybridisation experiments. This transcription of the transposed plasmid segment by the plant tumour cells suggests that it codes for one or more proteins which could have functional significance in inducing and/or maintaining the tumour syndrome. A major role of the bacterial plasmid, therefore, is to contribute a segment of new genetic information to the plant cell, and the translation of these plasmid genes in the plant, as suggested by the RNA transcripts, may be essential to the process. In many respects, therefore, the crown gall transformation process seems to parallel the events which occur in the induction of animal tumours by viruses.

Several traits in addition to that essential for virulence have been localised on the *Agrobacterium* plasmid. The ability of the bacterium to utilise either octopine or nopaline, unique N^α substituted derivatives of arginine, was shown to be highly correlated with virulence (Lippincott *et al. J. Bact.* **116**, 378; 1973) and loss or gain of the plasmid is accompanied by corresponding changes in utilisation of these compounds (Watson *et al. op. cit.*; Van Larebeke *et al. op. cit.*). Typically, the tumours synthesise one or the other of these arginine derivatives and the derivative synthesised is the same as can be utilised by the strain which induced the tumour (Petit *et al. Physiol. Veg.* **8**, 205; 1970; Bomhoff *et al. Molec. gen. Genet.* **145**, 177; 1976). A second plasmid gene is responsible for the ability to induce tumour synthesis of these compounds (Klapwijk *et al. J. gen. Microbiol.* **96**, 155; 1976; Montoya *et al. J. Bact.* **129**, 101, 1977).

This remarkable ability of agrobacteria to induce plants to synthesise compounds which the bacteria can utilise specifically as both a carbon and nitrogen source may well provide the *raison d'être* of this pathogen-host relationship. The finding that plasmid transfer

is greatly promoted *in vitro* by octopine (Kerr *et al. op. cit.*; Genetello *et al. op. cit.*) suggests that these compounds function similarly in the bacterium-tumour complex, promoting the plasmid exchange observed here. The tumours may thus provide both the stimulus and the nutritional requirement to accomplish gene transfer in the agrobacteria. It is also proposed that the enzymes responsible for octopine or nopaline synthesis in these tumours might be coded by bacterial genes (Petit *et al. op. cit.*) and recent plasmid results suggest that one of the plasmid genes which is transcribed in the tumour could be involved. No agreement exists, however, as to whether these arginine derivatives are normal plant products or are present only in these tumours.

Exclusion of *Agrobacterium* phage AP1 (Van Larebeke *et al. op. cit.*) and, in some nopaline-utilising strains, sensitivity to a unique bacteriocin of *Agrobacterium* strain K84 (agrocin 84, Roberts *et al. Nature* **265**, 379; 1977) is determined by the plasmid (Engler *et al. Molec. gen. Genet.* **138**, 345; 1975; Watson *et al. op. cit.*). Selection for resistance to agrocin 84 frequently results in plasmid loss or a deletion of portions of the plasmid essential for virulence. This has found practical application through use of strain K84 to control *Agrobacterium* infections in horticultural conditions (New & Kerr *J. appl. Bact.* **35**, 279; 1972). The plasmid also carries a gene which determines the ability of the bacterium to adhere to infection sites, an essential step in tumorigenesis (Whatley, dissertation, Northwestern Univ; 1977).

At least two plasmid genes seem to be functional in the transformation process in addition to adherence, because certain non-virulent strains which also carry a plasmid can increase tumour initiation when inoculated with virulent bacteria in conditions where bacterium-to-bacterium plasmid transfer is not observed (Lippincott *et al. J. Bact.* in the press). Indirect evidence suggests that the virulent bacteria produce or induce a diffusible product other than the intact plasmid which permits tumour initiation by the non-virulent strain. Obviously, much has to be learned about the nature of the genes localised on that part of the plasmid which is replicated in the tumours, as well as the genes and functioning of the much greater part of the plasmid which is excluded. The need for such a large plasmid is in itself an enigma. The possibility that *Agrobacterium* chromosomal genes are also directly involved in tumorigenesis is neither proven nor disproven.

Tumorigenic agrobacteria may now be counted the first cellular organisms demonstrated to accomplish in nature

the genetic engineering feat of transfer and stable incorporation of foreign DNA into a eukaryotic cell. These newer results also provide the first convincing indication that DNA from a prokaryotic cell may contain the appropriate base sequences to permit replication, transcription and possibly translation by the normal cellular machinery of eukaryotic cells. While important details of this transforma-

tion have yet to be established, the exciting prospects of genetic engineering for the production of beneficial changes in crop plants assures that they will be forthcoming. The transfer of nitrogen-fixing genes of *Rhizobium* to the closely related agrobacteria and subsequently to various plant hosts is but one example of the possibilities which are already receiving attention (*Science* **196**, 640; 1977). □

Are galactic γ rays point sources or diffuse emission?

from J. J. Quenby

A WEALTH of positive results from the SAS 2 and COS B satellites has firmly established the science of γ -ray astronomy, although as recently as 1970 the usefulness of making comprehensive searches for these high energy cosmic photons was actively debated. However, while the information acquired is clearly significant, what is still not clear is exactly which branch of astrophysics is being served by the measurements. A letter by Hermesen *et al.* in this issue of *Nature* (page 494) illustrates the difficulties involved.

γ -Ray emission is expected from the galactic disk by virtue of the interaction of cosmic rays with the residual matter in the interstellar medium. Although these charged, relativistic, cosmic ray particles may fill an extended galactic halo region (see *Nature* **268**, 401; 1977), it is only in the galactic disk that sufficient hydrogen atoms, at a density of about 1 cm^{-3} , are encountered for detectable γ -ray emission to occur. The π^0 mesons arising from the cosmic ray interactions decay into two γ rays producing a broad spectrum of photons. Any variation in the galactic longitude distribution of the resulting emission from the Milky Way should yield information on the spatial distribution of cosmic rays, provided the matter density is well established from other astronomical evidence.

The surprise arising from the earliest detection of γ rays from near the galactic centre by Kraushaar *et al.* (*Astrophys. J.* **177**, 341; 1972) on board OSO-111 was the unexpectedly high intensity, implying that cosmic rays are much more numerous at the centre than far out in the disk, near the Sun.

J. J. Quenby is in the Blackett Laboratory at Imperial College, London.

Maybe there are more cosmic-ray sources at the centre of the galaxy, but particle diffusion along the spiral arm magnetic fields needs to be well constrained to maintain this apparent gradient in number density. The SAS 2 γ -ray detector provided the first comprehensive survey of the galactic plane emission (Fichtel *et al. Astrophys. J.* **198**, 163; 1975) and the results show a reasonable correlation of γ -ray intensity with matter density in the spiral arms lying between us and the galactic centre. Furthermore, some of the discrepancy between the observed flux and that expected if cosmic rays were uniformly distributed in the Galaxy has been removed by including in the matter density the amount of molecular as opposed to atomic hydrogen, as estimated in an analysis performed by Scoville and Solomon (*Astrophys. J.* **187**, L67; 1974). However, an increase of a factor of two in the cosmic ray intensity is still needed in the inner spiral arm regions (Stecker *Phys. Rev. Lett.* **35**, 188; 1975). Moreover, at the Cosmic Ray Conference this August, several workers were concerned whether or not cosmic rays could actually easily penetrate the expected high magnetic fields within the dense clouds where molecular hydrogen is important (Cesarsky *et al.* and Strong *et al. Plovdiv C.R. Conf.* **1**, 61, 55; 1977).

The ESA satellite COS B is devoted entirely to a γ -ray detector constructed by six West European groups and data from this instrument have now provided more detail on parts of the galactic disk longitude distribution of emission. A particular feature of the results is the number of 'point' sources revealed in an incomplete survey with a 2.5° angular resolution. In 160° of longitude, Hermesen *et al.* find 13 sources,

10 of which are COS B discoveries. Two sources, the Crab and Vela, are known pulsars in supernovae remnants, one is possibly the strong X-ray source Cyg X-3, but the other 10 have either a weak or no association with soft X-ray sources or radio pulsars. They may be point-like or emission regions up to 2° wide. One may be associated with a source of hard X-rays seen by Ariel 5 (Coe *et al.* *IAU Circ.* No. 3003, 1976). Hermsen and colleagues stress that the γ -ray sources contribute significantly to the overall γ -ray luminosity of the Galaxy. Indeed, as pointed out by Strong *et al.* (12th *ESLAB Symposium, Frascati*, 1977), removal of point sources leaves very little evidence for a diffuse galactic emission from and beyond the Perseus arm, just outside 10 kpc from the galactic centre. It is tempting to conclude from the much increased fine structure seen in the COS B γ -ray intensity distribution that point source emission dominates and that little information on galactic cosmic ray motion can be gained by study of the disk photon emission.

Attacking the problem from the other end of the spectrum, the

Imperial College group have suggested that at least 8 (maybe >16) galactic hard X-ray sources may plausibly be extrapolated into the γ -ray region to account for a significant amount of the local γ -ray intensity (Plovdiv *C.R. Conf.* 1, 152; 1977). However, conventional accretion models for X-ray sources involving essentially thermal heating processes have difficulty in explaining γ -ray emission and a young pulsar model requiring electromagnetic acceleration would seem to be necessary, as invoked by Lamb *et al.* (*Astrophys. J.* 212, L63; 1977) to explain possible γ -ray production in Cyg X-3.

Until the contribution of point sources to the galactic disk emission is resolved, γ -ray astronomers cannot know whether they are chiefly contributing to knowledge of cosmic ray motion in the Galaxy or studying an important class of high energy photon sources involving non-thermal particle acceleration. Better angular resolution and sensitivity throughout the hard X-ray and γ -ray detector range is required to resolve this particular problem. □

3C 273 has an optical jet, a detached radio source (A) and a central source in which the radio object 3C 273 B has at least three components with milli-arc s diameters. Recent long baseline interferometer measurements (Legg *et al.* *Astrophys. J.* 211, 21; 1977) show that the radio variability is concentrated in one of these three components, on the NE (anti-jet) side of the nucleus. Assuming that the radio emission is synchrotron, the magnetic field in this component appears to be about 10^{-2} gauss (10^{-6} T). This field is very low in comparison with the stellar surface fields usually responsible for circular polarisation and it seems unlikely that this variable radio source can be the origin of circularly polarised optical emission. This must instead be related to the nucleus where much stronger magnetic fields might be encountered. Presumably the linear polarisation which is now observed to vary also originates in the nucleus.

The interesting aspects of the observations now reported are the rapidity of the variations both at radio and optical wavelengths, and the connection they seem to give between the NE radio component and the nucleus. If the results can be confirmed they should give a more coherent picture of the way in which the nucleus is pumping energy into the outlying sources, which is a crucial question in the origin of the extended radio sources frequently associated with quasars and radio galaxies. □

Polarisation in quasars

from F. Graham Smith

THE famous quasar 3C 273, which was the first to be shown to be both a radio source and an optical object with large red-shift, has been studied by every conceivable technique at radio, infrared, optical and X-ray wavelengths. It has spatial structure, a complex spectrum and polarisation, all of which vary with time scales between days and years. The physical processes behind these variations are practically unknown, and observers must sometimes despair of the possibility of making the key observation which will lead to an unravelling of the complex knot of behaviour. The paper from the Crimean Observatory (in this issue of *Nature*, page 493) puts a little order into the great variety of behaviour by showing that some of the radio and optical variations are related. The work has involved measurements of polarisation, both optical and radio, which have been difficult to make and which were for some time in doubt.

Variations in radio flux from 3C 273 were well known in 1966. They are most marked at short wavelengths: at 40 cm not much happens, but at 2 cm the flux density varies by a large factor. The spectra of several quasars

show these variations, which indicate an activity close to the core of the quasar, giving a rapid rise in radio emission first at short wavelengths and later, with less intensity, at longer wavelengths. Aller and Haddock at Michigan found that these variations were accompanied by changes in radio polarisation.

Optical polarisation was naturally searched for at this time, and indeed there was already a positive result by W. Liller in 1963, who reported verbally to the American Astronomical Society. Appenzeller concluded in 1968 that there was 0.26% linear polarisation, probably of interstellar origin. Results from the 2.6 m Crimean telescope then suggested the existence of circular polarisation, but at such a low level that the techniques were questionable. The observations were made at the coudé focus after several reflections, which easily create spurious polarisation. In 1972 these observations were restarted at the Cassegrain focus, with a more symmetrical optical system and checks with stars with well established circular polarisation showed a measuring accuracy of 0.01%. Both radio and optical observations of polarisation are achieving truly remarkable sensitivity.

F. Graham Smith is Director of the Royal Greenwich Observatory.

Electrophysiology of the hypothalamus

from J. L. Barker

A symposium on the Electrophysiology of the Hypothalamus was held at Hemingford Grey House in Cambridge on 24–26 July in conjunction with the 27th International Physiological Congress in Paris. It was organised by R. Dyer (ARC Cambridge) and R. Dyball (ARC Cambridge).

THE hypothalamus is associated with many bodily functions including autonomic reflexes, feeding and sexual behaviour, neuroendocrine control of anterior pituitary activity, thermoregulation and probably, metamor-

J. L. Barker is in the National Institute of Neurological and Communicative Diseases and Stroke, National Institutes of Health, Bethesda, Maryland.

phosis and hibernation. The symposium produced illuminating discussion on the electrophysiological basis of these involuntary activities crucial to the survival of the animal.

The initial aim of those in the field has been to correlate specific circuits with specific functions. However, unlike the cerebellum, cortex and hippocampus, where considerable circuitry has been delineated but where function remains unclear, the hypothalamus is replete with many short-range neurones and complex connectivity, making simple correlation of excitability with specific functions exceedingly difficult. In spite of this many of the contributors to the symposium attempted this correlation.

Those investigations focused on the magnocellular nuclei in the hypothalamus have achieved some measure of success, owing to the apparent homogeneity of magnocellular neurones and their dominant projection to the posterior part of the pituitary. Two populations of neurosecretory cells in these nuclei synthesise, transport and secrete vasopressin and oxytocin into the peripheral circulation to regulate plasma osmolality and various types of smooth muscle contractility. The long projections of the cells have been used to locate the parent cell bodies in the nuclei, since electrical stimulation of the terminal causes 'antidromic' activation of the cell bodies, thus indicating whether the neurone recorded from projects to the posterior pituitary.

Significant contributions to the physiology of these neurosecretory cells have been derived from experiments using natural stimuli. These studies show that one population of neurones is induced to fire in a characteristic 'phasic' manner following circulatory compromise while another group is activated by suckling pups (J. D. Vincent and D. Poulain, University of Bordeaux; Dyer, Dyball and J. B. Wakerley, ARC Cambridge; D. W. Lincoln, University of Bristol; J. J. Dreifuss, Ecole de Médecin, Geneva; H. Yamashita, State University of New York, Brooklyn). The former are assumed to be vasopressin-secreting neurones, while the latter are considered to be oxytocin-secreting cells, because the two different stimuli have been shown to release in a specific and independent manner each of the two neurohormones. Thus, two populations of neurones in the magnocellular nuclei have been tentatively identified by their electrophysiological responses to natural stimuli. The presumed vasopressin cells seem to generate phasic activity independent of each other, while the presumed oxytocin neurones fire high-frequency bursts in a synchronised manner. Not yet established is whether the phasic firing pattern is

a latent, endogenous property of these cells which is activated with appropriate stimuli, as happens in a variety of invertebrate neurosecretory cells, or whether the pattern is synaptically derived. Likewise, the synchronised burst of oxytocin neurones may represent electrical coupling among the elements, as occurs in some invertebrate neurosecretory cells, or it may reflect common synaptic input. Definite relationships between hormone release and electrical activity were demonstrated by Dyball, Lincoln and K. Boer (Netherlands Institute for Brain Research, Amsterdam), all of whom showed that clustering of spike activity into phases or bursts produces considerably more neurohormone output than random, unclustered spike activity. Some clue to membrane mechanisms underlying this facilitated, pulsed release is suggested by studies on invertebrate neurosecretory cells which show that the conductance responsible for spike repolarisation accommodates during bursts (J. L. Barker and T. Smith, National Institutes of Health, Bethesda), thus progressively prolonging individual spikes in a burst and allowing facilitated entry of Ca^{2+} and release of neurotransmitter or neurohormone. Pulses of oxytocin are apparently necessary for lactation, since a constant, low level of hormone is ineffective.

Although considerable effort has been expended on the parvocellular elements in the hypothalamus, most notably by L. P. Renaud (McGill University, Montreal), R. L. Moss (University of Texas, Dallas), B. Dufy (University of Bordeaux), M. C. Harris (University of Birmingham) and K. Yagi (Jichi Medical School, Tochigi-Ken), definite conclusions regarding the roles of these cells in hypothalamic function have yet to be made. This impasse derives mainly from the interconnectivity of the cells, as well as a lack of systematic identification of recorded cells by combined marker stains and immunohistochemistry techniques. The complexity and lack of clear organisation among these hypothalamic elements has caused immense difficulties in specifying the circuits and electrophysiological bases of thermoregulation, sex, autonomic and nutritive behaviour. Some progress has been made by E. T. Rolls (University of Oxford) who has demonstrated hypothalamic units specifically responding to visual stimuli conveying information about food. Mapping of those units conveying information about central and peripheral temperature is being done by those interested in thermoregulation, including R. F. Hellon (National Institute for Medical Research, London), D. Ford (St Bartholomew's Hospital, London),

J. A. Boulant (Ohio State University, Columbus), and J. T. Stitt (Yale University, New Haven). Another line of research, using the push-pull cannula method to apply to, and sample from the hypothalamus various neuroactive substances, has revealed some of the substances released during specific behaviour (R. D. Myers, Purdue University, West Lafayette).

One may conclude from this symposium that the understanding of the cellular basis of assorted hypothalamic functions is fragmentary at best, and that although definite progress has been made, far more research, making use of natural stimuli and multidisciplinary approaches, is required to begin to unravel what is certainly an immensely complex area of the nervous system. □

Identifying carcinogens

from Alastair Hay

An Ecotoxicology Workshop was held at the University of Surrey from 11 July to 5 August under the auspices of the Eco-Sciences Panel of NATO. The third week of the workshop was taken up by an International Symposium on Industrial Toxicology—the seventh such meeting held at the University of Surrey.

SOME of the problems in identifying possible carcinogens were exemplified during the workshop by work presented on the azo dye butter yellow (I) and the 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) released in the Séveso accident. Butter yellow is a known liver carcinogen whereas TCDD is as yet only under suspicion (see *Nature* **258**, 2; 1975) but reports of the behaviour of these chemicals in the tests currently used to identify potential carcinogens well illustrate the problems involved.

Because animal studies are expensive and take a long time much work has been done on developing reliable short-term tests for initial screenings. But in view of the large number of compounds jockeying for attention, pre-selection of chemicals to be submitted to the screen on the basis of structural and physicochemical resemblances to known carcinogens is an attractive proposition. This is the approach advocated by a group of workers at ICI and

(III)

(IV)

(V)

(VI)

at the workshop John Ashby and his colleagues (ICI, Alderly Park) reported experiments testing the effects of structural modifications of butter yellow on its performance in one of the short-term tests.

Butter yellow gives a predominantly negative response in the Ames test (which tests the ability of a chemical to cause mutations in bacteria). It does, however, give a reproducible positive response in the Styles cell transformation test (*Br. J. Cancer*, in the press). The 3-methyl analogue (II) reported to be non-carcinogenic in animal studies proved negative in this test as well, as might be expected on theoretical grounds. The 3-methyl group forces a change in the angle of the NMe_2 group with respect to the benzene ring. This would reduce or abolish the stability of the nitronium ion thought to be involved in the binding of compounds such as (I) to DNA (Lin *et al. Cancer*

Res. **35**, 844; 1975). To check the importance of the angle change in the carcinogenic deactivation of (II) Ashby *et al.* synthesised and tested the indoline (III). Here the overall substitution pattern is the same, but by joining the 3-methyl group to one of the NMe_2 groups planarity between the nitrogen base pair of electrons and the benzene ring is restored.

In the Styles assay (III) was positive. So far no derivatives of the indoline have been tested *in vivo* for carcinogenicity, but these results suggest that it might be a liver carcinogen. If this turns out to be true it would strengthen the theoretical basis for the difference in activity between (I) and (II).

Curiously the NEt_2 analogue (IV) of butter yellow is reported to be non-carcinogenic, whereas the 4'-ethyl analogue (V) is a carcinogen. The small structural change involved in the addition of an ethyl group to (IV) would hardly be expected to reintroduce carcinogenicity if a fundamental principle were involved in the activity of (IV). Needless to say both (IV) and (V) were positive in the Styles assay. This suggests that either (IV) has been inadequately tested in animals for carcinogenicity, or that perhaps some nonspecific and secondary mechanism such as its solubility, or transport into the cell prevented it from producing tumours *in vivo*. The Styles assay clearly predicts (IV) as a potential carcinogen, and surely represents an efficient short-term test. But the Styles assay does fail to predict β -naphthylamine as a carcinogen whereas this compound produces a positive response with the Ames test. Clearly both tests are necessary for a screening net of finer mesh.

TCDD presents a more complex problem. It is a planar tricyclic aromatic compound (VI) said to be chemically similar to many polycyclic hydrocarbon carcinogens which bind to DNA directly or through the formation of a metabolite (Poland & Kende *Fedn Proc.* **35**, 2404; 1976), or to the acridines which intercalate in DNA (Hussain *et al. Ambio* **1**, 1; 1972). In fact the chemistry of TCDD is not like that of the known carcinogens. Whereas the carbon atoms which bridge the benzene rings in the tricyclic aromatic carcinogens form part of a conjugated bond system, this is not true of the oxygen atoms in TCDD. The oxygens do not conjugate to the benzene rings. From a structural point of view, therefore, TCDD would not be expected to be a carcinogen. The possibility exists, however, that ring epoxidation may occur *in vivo* to convert it into a potential carcinogen. But the metabolism of TCDD, if it does occur, is very slow (Piper *et al. Environ. Health Perspect.* **5**, 241; 1973).

From the evidence available it seems that TCDD is not mutagenic in all bacterial systems. It is reported to be mutagenic in *Escherichia coli* Sd-4 (Hussain *et al., op. cit.*) and *Salmonella typhimurium* TA 1532 (Hussain *et al., op. cit.*, Seiler, *Experientia* **29**, 662; 1975) but not in the *S. typhimurium* strain TA 1530 (Hussain *et al., op. cit.*). Ames and Yamasaki (quoted in Poland & Kende, *op. cit.*) were unable to demonstrate reversion of specific mutant strains of *S. typhimurium* by TCDD treatment.

The only animal study to test the carcinogenic potential of TCDD so far reported is that of Van Miller and Allen (*Fedn Proc.* **36**, 396; 1977). These authors report that in rats TCDD causes carcinomas of the kidney, liver and skin as well as angiosarcomas. This is a disturbing claim which urgently requires confirmation. It is fortunate, therefore, that two other animal studies are nearing completion—those of the Dow Chemical Company and US National Cancer Institute. Their results are awaited eagerly.

It should perhaps come as no surprise that the clinical data on TCDD's potential mutagenic or carcinogenic properties are mixed. G. Reggiani (Hoffmann-La Roche, Basle) reviewed the clinical picture of 800 cases of presumed TCDD exposure in workers—all of whom developed chloracne—exposed to the chemical during the production of 2,4,5-trichlorophenol. The frequency of chromosomal abnormalities in these workers and their families is no greater than the statistical norm. As for the incidence of cancer, the evidence from two factory studies at the Spolana plant (Czechoslovakia) and BASF site (Germany) suggests that the rate is not increased in workers exposed to the dioxin.

Claims to the contrary come from Vietnam. An increase in liver cancer in individuals exposed to the herbicide 2,4,5-T in which TCDD is present as a contaminant may be attributable to the dioxin (Tung reported in *Galston Nature* **258**, 2; 1975). A preliminary study by Tung *et al.* (*Vietnamese Studies* **29**, 53; 1971) also reports an increased incidence of chromosomal abnormalities in the victims of herbicide spraying. The Vietnamese study has been criticised (*Effect of Herbicides in South Vietnam*, National Academy of Sciences, 1974) as being statistically inadequate. It is being repeated, but on a larger scale.

G. Tognoni (Mario Negri Institute, Milan) found the Vietnamese reports disturbing. Although no evidence of chromosomal abnormalities has so far been observed in the Séveso population he was far from optimistic about their long term health prospects.

There is obviously an urgent need

to resolve the question of whether or not TCDD is a potential carcinogen. The Van Miller and Allen study is the only one so far which claims that it is. Their claim needs to be supported by experiments in other animal species. Other short term tests could also be applied; the results from these could perhaps clear up the conflicting evidence. □

Degradative plasmids

from J. R. Saunders

MEMBERS of the bacterial genus *Pseudomonas* are renowned for their capacity to utilise an enormous range of compounds as energy and carbon sources. Over the past few years it has become clear that the ability of these organisms to degrade certain exotic substrates is specified by genes borne on plasmids. A variety of such 'degradative plasmids', some of which are self-transmissible, has been identified (see Chakrabarty *A. Rev. Genet.* **10**, 7; 1976). Thus plasmids can confer on host pseudomonads the ability to break down naphthalene (NAH plasmid), salicylate (SAL plasmid), camphor (CAM plasmid) *n*-octane (OCT plasmid) and toluene and xylenes (TOL plasmid).

TOL plasmids carry the genes encoding the degradation of benzoate and *m* and *p*-toluates by way of the *meta* (α -ketoacid) pathway in *P. putida*. A functional *meta* pathway is also specified by other degradative plasmids. It involves a single set of enzymes allowing growth on a wide range of hydrocarbons, aldehydes, alcohols and carboxylic acids, all of which may present themselves as potential sources of nutrition in the wild. Furthermore, the location of the genetic determinants for the *meta* pathway on plasmids increases versatility by assisting the spread of the degradative trait in the bacterial population. In common with many other saprophytic pseudomonads, *P. putida* possesses an alternative route for dissimilation of benzoate, the *ortho* (β -ketoadipate) pathway. The *ortho* pathway is chromosomally determined and like the *meta* pathway initially involves the oxidation of benzoate to catechol. Subsequently the pathways diverge: the *ortho* pathway requires the conversion of catechol to *cis-cis* muconate by catechol 1,2 oxygenase, the product in this case being the inducer for the enzyme. In contrast benzoate itself probably initiates expression of the *meta* pathway by inducing catechol 2,3 oxygenase which

converts catechol to hydroxymuconic semialdehyde. Consequently when the genes for both pathways are present, as in a Tol⁺ strain of *P. putida*, benzoate is preferentially degraded by the plasmid-coded *meta* pathway and not the chromosomal *ortho* pathway. way.

Ironically Mike Worsey and Peter Williams (*J. Bact.* **130**, 1149; 1977) have found that some strains of *P. putida* grow faster on benzoate when using the *ortho* pathway. Thus growth of such strains on benzoate exerts a selective pressure for loss of Tol function. This may be by elimination (curing) of the entire 78 Mdal TOL plasmid or by deletion from the plasmid of a specific segment of about 27 Mdal which encodes all or part of the TOL pathway (Bayley *et al. Molec. gen. Genet.* **154**, 203; 1977). Growth on benzoate can also select for strains which have an intermediate (B3) phenotype. These can still grow on toluene, *m*-xylene and benzoate but are incapable of using *m*-toluate. Strains of the B3 phenotype apparently possess a regulatory mutation which blocks induction of *meta* pathway enzymes by benzoate and *m*-toluate but enables induction by toluene and *m*-xylene. It is envisaged that early enzymes for utilisation of *m*-toluate and benzoate are positively controlled by two separate regulators, one of which interacts with the inducers toluene and *m*-xylene, whereas the other (lacking in strains of B3 phenotype) interacts with benzoate and *m*-toluate. Further studies on the genetic regulation of this and other degradative pathways promise to be of great interest.

Peter Williams and coworkers at the University of Wales, Bangor, in collaboration with Paul Broda's group at the University of Edinburgh have also characterised the plasmids in thirteen Tol⁺ pseudomonads isolated from soil samples in different geographical locations (Duggleby *et al. J. Bact.* **130**, 1274; 1977). They have assigned the TOL genes to a number of plasmid species in different organisms. Interestingly five of these plasmids are indistinguishable on the basis of their molecular weights (all about 77 Mdal) and gel electrophoresis profiles after endonuclease digestion. One member of this apparently homologous series of plasmids was resident in a strain isolated in Japan whereas the other host strains were found in Wales. This implies widespread distribution of a single TOL plasmid. Although worldwide spread of particular R plasmids is well documented and explicable in terms of international travel and human contact, it is harder to see how a single degradative plasmid could become broadcast amongst the population of soil bacteria. One possibility

would be the spread of carrier strains by large scale import and export of industrial materials such as oil products contaminated with soil bacteria.

Degradative plasmids obviously contribute greatly to the already substantial nutritional versatility of *Pseudomonas* species. Many of the compounds degraded under the control of such plasmids would otherwise be toxic to other forms of life. Such degradation is therefore of some importance in detoxifying localised areas of pollution. Indeed it has been proposed that *Pseudomonas* strains carrying degradative plasmids be used to disperse oil spillages and render them harmless. Since most of the degradative plasmids belong to different incompatibility groups it is possible to construct pseudomonads which carry a battery of different degradative plasmids which together confer enhanced ability to utilise crude oil. Chakrabarty, who has been a prominent advocate of this approach, has pointed out that such strains would also have to harbour mercury-resistance plasmids to cope with the high levels of the heavy metal in oil residues.

The deliberate introduction of such constructed strains into the environment is open to the same kinds of objections as those levelled against recombinant DNA research. Such ventures could rebound if for example they led to the breakdown of petroleum products in storage tanks or the induction of pathogenic characteristics in previously harmless saprophytic species. However initial studies on the 'epidemiology' of TOL plasmids indicate that the population of soil bacteria has itself already responded to the increasing load of organic pollutants that has leaked into the environment. Selective forces, analogous to those that have led to the spread of antibiotic resistance in clinically important bacteria, are probably operating to produce bacteria that are resistant to and able to degrade industrial pollutants. In this case the consequences for mankind should be beneficial. □

Thresholds and breakpoints in ecosystems with a multiplicity of stable states

Robert M. May*

Theory and observation indicate that natural multi-species assemblies of plants and animals are likely to possess several different equilibrium points. This review discusses how alternate stable states can arise in simple 1- and 2-species systems, and applies these ideas to grazing systems, to insect pests, and to some human host-parasite systems.

IN all but the most trivial areas of enquiry, there arise questions about the extent to which events are shaped by predictable natural laws as against the accidents of initial conditions and perturbations. Is the human story largely a deterministic tale of civilisations marching to Toynbee's tune, three and a half beats to disintegration, or did the hinge of history turn on the length of Cleopatra's nose? Such questions of the relative roles of chance and necessity¹ are fundamental in modern cosmology^{2,3}, in the foundations of statistical mechanics^{4,5}, and in evolutionary biology¹ and ecology, even though they may arise in less blatant and romantic fashion than the 'what ifs' of history and the social sciences.

Viewing the grand sweep of evolution, we can see many examples where the taxonomic details of the plant or animal that occupies a given niche at a given time and place depend on historical accident, but where the niches themselves, and the broad patterns of community organisation, are remarkably constant⁶⁻⁹.

Taking a much narrower and more local view, it is interesting to consider a particular assembly of species, with specified interactions among them, and to ask questions about the dynamics of the system. Is the dynamical behaviour described by the multi-dimensional generalisation of a single valley (a global attractor)? Or is the dynamical landscape pockmarked with many different valleys, separated by hills and watersheds? If the former, the system has a unique stable state, to which it will tend (like a marble seeking the bottom of a cup) from all initial conditions, and following any disturbance. If the latter, the state into which the system settles depends on the initial conditions; the system may return to this state following small perturbations, but large disturbances are likely to carry it into some new region of the dynamical landscape (so that the system behaves rather like the ball in a pin-ball machine). If there is a unique stable state, historical effects are unimportant; if there are many alternative locally stable states, historical accidents can be of overriding significance. Obviously, questions of this kind are very important in the understanding and management of ecosystems.

A large body of empirical observations shows that many natural communities have a multiplicity of stable states. Sutherland¹⁰ has demonstrated that for the fouling community (a complex assembly of hydroids, tunicates, bryozoans, sponges and associated species) at Beaufort, North Carolina, the order of larval recruitment determines the way the community develops. Reviewing other work on the marine rocky intertidal (see also the review by Levin¹¹), on coral reefs, on freshwater lakes, and on terrestrial plant communities, Sutherland concludes that community structure can often "be explained only by referring to specific historical events" and therefore that "multiple stable points are an undeniable

reality." A similar conclusion emerges from Connell's and Slatyer's¹² survey of mechanisms of succession in natural communities.

The view that complicated ecosystems possess many alternative stable states is also supported by theoretical studies of mathematical models that caricature such systems. From the growing number of possible examples, I mention only two, chosen from opposite ends of the spectrum. Austin and Cook¹³ have made computer studies of a system in which 94 species (embracing plants, herbivores and carnivores) are linked together by interactions that aim to be relatively realistic; the system has many equilibrium points, and is easily transferred from one to another. Case and Gilpin¹⁴ have explored a relatively abstract system, in which the coefficients in the interaction matrix for a n -species Lotka-Volterra model are assigned random values; if n is at all large, the system typically collapses to one or other of a variety of simpler systems with fewer species, and this final steady state depends on the initial population values. The notion of 'resilience' has been introduced by Holling¹⁵ in an attempt to characterise the degree to which a system can endure perturbations without collapsing or being carried into some new and qualitatively different state. Theoretical ideas about resilience, along with interpretive reviews of diverse other meanings that can be attached to 'stability' in an ecological context, are the subject of many recent papers¹⁶⁻²².

It is thus clear that real ecosystems possess multiple stable states, as do plausible mathematical models. Unfortunately, the complications inherent in multi-species systems almost invariably preclude any quantitative confrontation between theory and data. For multi-species communities, the empirical observations remain largely anecdotal, and the theory remains largely metaphorical.

For simple 1- and 2-species situations it is, however, beginning to become possible to put theory and observation together, to gain insight into the workings of systems with more than one stable state. This review is a synthesis of several examples of this kind. I begin with grazing ecosystems (and then, more generally, any harvested crop or animal population), go on to insect pest systems (particularly the spruce budworm), and conclude with some human host-parasite systems.

Grazing ecosystems

Consider^{23,24} a population of herbivores, maintained at a constant density H , and sustained by vegetation whose biomass is V .

Our interest is centred on the dynamics of the vegetation biomass. Following Noy-Meir²³, suppose that in the absence of grazing the growth rate of the vegetation as a function of V is $G(V)$, and that the herbivores consume the vegetation at a net rate $C(V)$ (corresponding to a per capita consumption at a rate $c(V)$: $C(V) = Hc(V)$). Then the rate at which V changes is given by

*Biology Department, Princeton University, Princeton, New Jersey 08540

$$dV/dt = G(V) - C(V) = G(V) - Hc(V) \quad (1)$$

The vegetation biomass will thus tend to settle to an equilibrium level where the natural growth rate exactly balances the loss rate due to grazing; that is, to a value of V such that $G(V) = C(V)$. Noy-Meir shows how these equilibrium V -values can be found graphically, for various assumptions about the way $G(V)$ and $C(V)$ depend on V .

Fig. 1 illustrates one plausible situation. Here, as shown by the solid curve, $G(V)$ is positive even when $V = 0$ (corresponding to some constant background contribution to the vegetation growth rate, for example from the sprouting of seeds blown in from other areas). At first $G(V)$ increases as V increases, but as V continues to increase $G(V)$ decreases as shading and competition for nutrients becomes important, until $G(V) = 0$ at $V = K$; K is the maximum stable biomass of ungrazed vegetation. The general shape of the per capita consumption function $c(V)$ is a saturation curve: at low V , the herbivore intake is limited by forage availability, so that $c(V)$ increases with increasing V ; at high V , $c(V)$ saturates to some constant determined by the animal's intake capacity or digestion rate. It is useful to christen V_0 as the characteristic value of V at which the consumption function saturates. The dashed curves for total consumption rate $C(V) = Hc(V)$ in Fig. 1 are for a $c(V)$ that increases linearly with V at small V , corresponding to a herbivore that searches randomly (Holling's "Type II" or "invertebrate" predator search pattern²⁵).

We see from Fig. 1 that for relatively small values of H there is a single equilibrium value for V , given by the point A where $G(V)$ and $C(V)$ curves intersect; this value is slightly less than K . For relatively large values of H , there is again a unique equilibrium value for V (corresponding to the point E), now at a low value of V . For intermediate values of H , the $G(V)$ and $C(V)$ curves intersect at three points. The points B and D correspond to locally stable V -values, whose domains of attraction are divided by the unstable equilibrium point corresponding to C; B and D are the bottoms of adjacent valleys, and C marks the watershed between them.

The essential feature that leads to two alternative stable states for intermediate H values in Fig. 1 is the assumption that $c(V)$ saturates to a constant for values of V significantly below the ungrazed equilibrium. That is, defining

$$\alpha = V_0/K \quad (2)$$

Fig. 1 is for α significantly less than unity. If α exceeds, or is of the

Fig. 1 The rate of change of vegetation biomass, dV/dt , is shown as a function of V . The solid curve is the natural, ungrazed vegetation growth rate (which here is finite even for $V = 0$). The dashed curves are loss rates due to grazing (of Type II pattern) at high, intermediate and low herbivore densities, H . Where the solid curve lies above the dashed one, the net growth rate is positive; where the solid curve lies below the dashed one, the net growth rate is negative; the points of intersection of the curves correspond to possible equilibrium points. For further discussion, see the text.

Fig. 2 As for Fig. 1, except that here the natural growth rate (solid curve) is linearly proportional to V at small V , and the loss rate due to grazing (dashed curves) is of Type III. Specifically, this figure corresponds to equations (3) and (4); the α of equation (2) is here $\alpha = 0.1$, and 'high, intermediate and low H ' are represented by $\gamma = 0.35, 0.22$ and 0.10 , respectively. The basic features shown by the figure are, however, generic.

order of, unity, there is always only one stable state in the figure corresponding to Fig. 1.

Fig. 2 illustrates another plausible circumstance, which differs from Fig. 1 in details but not in essentials. Here, as V increases, $G(V)$ increases from zero to some maximum value and then decreases back to zero at $V = K$. The per capita consumption function $c(V)$ is now for herbivores whose foraging efficiency increases faster than linearly with V at low V values, but which again saturates to a constant for V above some characteristic value V_0 (Holling's "Type III" or "vertebrate" predator consumption function²⁵, which is also typical of many invertebrates²⁶⁻²⁸). Provided that V_0 is significantly less than K (that is, α is small), we can again distinguish three domains of dynamical behaviour for the vegetation biomass: for small H there is a unique equilibrium value of V , slightly below K (the point A); for large H there is a unique equilibrium at a low V value (the point E); for intermediate H there are two alternative stable states (the points B and D), divided by an unstable point (C).

Specifically, Fig. 2 illustrates the situation where $G(V)$ is given by the familiar logistic equation, $G(V) = rV(1 - V/K)$, and where $C(V)$ is the "Type III" consumption function $C(V) = \beta HV^2/(V_0^2 + V^2)$. Then equation (1) has the particular form

$$\frac{dV}{dt} = rV \left(1 - \frac{V}{K}\right) - \frac{\beta HV^2}{V_0^2 + V^2} \quad (3)$$

This equation may equivalently be written in dimensionless form, by using the earlier definition of α , and introducing the rescaled variables $X = V/K$, $\tau = rt$ and $\gamma = \beta H/rK$

$$dX/d\tau = X(1 - X) - \gamma X^2/(\alpha^2 + X^2) \quad (4)$$

This equation can exhibit (D. Ludwig, D. Jones and C. S. Holling, to be published) two alternative stable states if, and only if, $\alpha < 1/\sqrt{3}$.

Figure 3 is derived from the situation depicted in Fig. 2, and shows the stable equilibrium value(s) of the vegetation V , as a function of the herbivore density H . For low H , the vegetation biomass tends to settle to a unique steady value, slightly below K . As H increases beyond a threshold value (T_1), a second stable state for V appears, in a discontinuous fashion. As H continues to increase, there occurs a second threshold (T_2), beyond which there is again only one stable equilibrium for V (the original low- H state having disappeared, discontinuously). For stocking densities in the intermediate region, $T_1 < H < T_2$, the vegetation will tend

Fig. 3 The equilibrium values of the vegetation biomass, V , are shown as a function of the stocking density, H . For a fixed value of H below the lower threshold at T_1 , or above the upper threshold at T_2 , there is a unique equilibrium value of V ; any initial V value will move to this equilibrium, as indicated by the arrows. For H between T_1 and T_2 , there are two alternative equilibria for V : as shown by the arrows, the system will move to the upper or lower equilibrium, depending on whether the initial value of V lies above or below the dashed 'breakpoint' curve. (This curve is constructed from Fig. 2 and equations (3) and (4), with $\alpha = 0.1$.)

toward either the upper or the lower equilibrium value, depending on the initial value of V : for initial values lying above the dashed line in Fig. 3, V will move toward the upper equilibrium; initial values below the dashed line will move to the lower equilibrium. Borrowing an epidemiological term²⁹, we may call the dashed line the locus of the "breakpoint" values of V .

Although Fig. 3 was constructed from the specific equation (3), its important features are generic to any grazing ecosystem where the dynamics of the vegetation biomass is described by something like Figs 1 or 2. Even in the specially simple case where the $G(V)$ of Fig. 2, with $G(0) = 0$, is combined with the $C(V)$ of Fig. 1, with a linear dependence on V for small V , we still obtain Fig. 3, except that now the lower equilibrium value (occurring for $H > T_1$) is $V = 0$.

If it is assumed that gross animal production, P_G , is linearly proportional to total consumption, $C(V)$, then the equilibrium level of P_G as a function of stocking density H can be read off from Fig. 3. This is done in Fig. 4. Fig. 4 has all the properties just adumbrated for Fig. 3, and is similarly generic.

Noy-Meir first points out some management morals implicit in all this, and then discusses the extent to which such theoretical insights accord with known facts.

If one has a grazing system capable of manifesting the discontinuities illustrated in Figs 3 and 4, then the vegetation will tend always to recover to a high level following an environmental disturbance only if H is kept below some threshold density, T_1 . But, as can be seen from Fig. 4, this usually implies unacceptably low gross productivity. Conversely, for H above T_1 , there is the danger that an environmental fluctuation will carry V below the breakpoint value (the dashed line), whereupon the system will move into the alternative steady state, with dramatically lower values of V and P_G . The closer the system is pushed toward the point of maximum productivity (at $H = T_2$), the more likely is this discontinuous collapse. And of course if the stocking rate for maximum productivity is misjudged, so that H is pushed beyond T_2 , then the system must collapse to the lower equilibrium state. As Noy-Meir²³ sums it up, "a discontinuously stable system is highly labile at the stocking rate which allows the highest productivity. Such a grazing system can be maintained at or near this maximum production rate only by very frequent, almost constant, adjust-

ments of stock density in response to fluctuations in vegetation. A somewhat lower stocking rate will ensure more stable, though on the average somewhat lower, production."

Noy-Meir reviews two classes of empirical evidence.

For intensive, or pasture, systems he pulls together data on the growth curves as a function of green biomass, $G(V)$, for ryegrass-clover in New Zealand^{30,31} and for clover in Australia³², and on the consumption curves for sheep, $C(V)$, for *Phalaris*-clover³³, for *Phalaris*-annuals-clover³⁴, and for ryegrass-clover³⁵, all in Australia. He concludes that the sheep tested by Arnold and by Willoughby would be capable of discontinuous stability properties in October (down under) in pastures of ryegrass, ryegrass-clover, and possibly in clover. There is also direct evidence for two alternate stable states in an experiment done by Morley³⁶, which involves sheep at three different stocking rates in two grazing systems (continuous and with rotation), with three replicates of each.

For extensive, or range, systems, indirect evidence can be culled from traditional management practices. Noy-Meir lists the conventional distinction between 'safe' and 'maximum' stocking rates, the notion of range readiness (allowing the vegetation to build to some pre-determined level before introducing animals), and the observation that productivity and animal condition may remain high even though the range is on the verge of collapse. This 'conventional wisdom' is readily justified by Figs 3 and 4.

Throughout this discussion, the herbivore density H has been treated as a constant. In natural (as opposed to managed) situations, H itself will be a dynamical variable, whose rate of change depends on V and H . The consequent pair of differential equations for $H(t)$ and $V(t)$ have been discussed by many people: see the review by Caughley²⁴. The system may have a unique stable point, or two (or even more) alternate stable points, or the populations may oscillate in a stable limit cycle. This subject will be pursued further, when we come to the budworm model, below.

Harvesting animal populations

In grazing ecosystems, we considered the dynamical behaviour of a population (the 'vegetation', $V(t)$) which was being harvested by herbivores. Much of the discussion can be translated to apply to other systems where a plant or animal population is harvested, either directly or indirectly, by man. In particular, fisheries provide an example where one is interested in the dynamics of a fish population, and where the net population growth rate involves a natural growth term, $G(V)$, and a loss rate due to harvesting, $C(V)$, which in general depends both on the fishing effort and on the fish

Fig. 4 Gross animal productivity, P_G , is shown as a function of H . This curve is derived from Fig. 3, under the assumption that P_G is proportional to the total consumption, $C(V)$, of equation (1). The main features are as in Fig. 3; for further discussion, see the text.

population density. The same is true of whaling industries, and of commercial forestries.

Brauer and Sanchez³⁷ have considered a fish or other population that is harvested to give a constant yield. Their analysis corresponds to Fig. 2 in the limit $\alpha \rightarrow 0$; that is, they have the $G(V)$ curve of Fig. 2, but their consumption or harvesting curves are purely horizontal lines, already saturated at $V = 0$. The resulting equilibrium fish population (V) as a function of yield (H) is a limiting version of Fig. 3, with T_1 at the origin, and the lower equilibrium curve collapsed to the H axis ($V = 0$).

Fig. 5 This figure is a difference equation version of Fig. 3, for animals with non-overlapping generations. The curves relating the population magnitudes in successive generations are shown for various levels of predation, P . Possible equilibrium points occur where the curves intersect the 45 line. (Specifically, the difference equation used here is $N(t+1) = N(t) \exp[r\{1 - N - PN(x^2 + N^2)\}]$, with $\alpha = 0.1$, $r = 4$, and $P = 0.35, 0.22, 0.15$.)

A more realistic harvesting curve will acknowledge that, at low fish population values, the effort needed to keep the yield constant is prohibitively high. Consequently, a realistic curve for attempted 'constant yield' harvesting will be more like those in Fig. 1 and 2, and much of the discussion of the system's dynamics (ref. 38 and J. R. Beddington, to be published) parallels that by Noy-Meir. Beddington and May's³⁸ study is focused on the response of the system to environmental fluctuations, and to this end employs differential equations with stochastic coefficients. Nevertheless, the qualitative conclusions of this relatively sophisticated study (especially the caution against trying to maximise sustained yield under a strategy of constant quotas, which is roughly equivalent to operating around T_2 in Fig. 4) are laid bare by the simple and deterministic graphical analysis outlined above.

Other recent studies of harvested systems which can have alternate stable states are due to Goh³⁹ and to Huberman⁴⁰ (who uses equation (3)). Clark⁴¹ has given a fine review.

Insect pests: general remarks

We now alter our viewpoint, to think of $V(t)$ more generally as a 'prey' population. Its dynamical behaviour depends on the trophic level above it (the 'predators', which were the herbivores H in the grazing systems) and on the trophic level below it (the resources, which were the light and nutrients determining K in the grazing systems). At the risk of confusing the reader, I shall symbolise this change of viewpoint by using $N(t)$, to replace $V(t)$, for the prey population, and by using P , to replace H , for the predators.

In dealing with insect pests, our attention has shifted up one rung in the trophic ladder. Instead of the vegetation $V(t)$ which

depends on a variable H and a constant K , we have a population $N(t)$ of herbivorous insects which depends on predators P and vegetational resources K , either of which may vary.

For a given value of the environmental carrying capacity (K) and for a specified density of predators (P , formerly H), the considerations that determine the dynamics of the prey population (N , formerly V) are likely to be as in Fig. 2. That is, the growth rate of the prey population may be typified as logistic, and the predators' attack rate will have the general form shown in Fig. 2 both for vertebrate²⁵ and for many invertebrate²⁶⁻²⁸ predators.

One final complication must be disposed of. For the majority of temperate zone insects, population growth is a seasonal (often annual), rather than a continuous, affair. Thus the continuous rate of population change, dN/dt , should usually be replaced by discrete changes, $N(t+1) - N(t)$, at time intervals one unit (often one year) apart. The relation between the population values in successive generations will still typically be determined by Fig. 2, but with $N(t+1) - N(t)$ replacing dN/dt on the y -axis. It is more traditional, in this case, to plot the curve that relates $N(t+1)$ to $N(t)$. This is done in Fig. 5. The 45 line represents population values that are unchanging from one generation to the next, and therefore the points where the curves intersect this line are possible equilibrium states. Where the solid curve lies above the dashed curve in Fig. 2, the net growth rate is positive, and the curve lies above the 45 line in Fig. 5. Conversely, where the solid curve lies below the dashed one in Fig. 2, the curve lies below the 45 line in Fig. 5.

When predation is relatively unimportant (low H in Fig. 2, low P in Fig. 5), there is a unique equilibrium point, at a population value slightly below K ; the population level is set primarily by resources. When predation is relatively important (high H in Fig. 2, high P in Fig. 5), there is again a unique equilibrium point, this time at a low population level; the population is predator-controlled. But for intermediate levels of predation there are, as before, two attracting equilibrium points (A and B in Fig. 5), divided by a repelling point (C in Fig. 5).

The consequences of this intermediate level of predation, with its two alternative equilibria for the pest population, have been noted by Takahashi⁴² and Watt⁴³. They observe that such pests may usually fluctuate at low numbers, around the lower equilibrium point at N_B . But if fluctuations in the number of predators, or of pests, or of the carrying capacity, happen to carry pest numbers above N_C in any one year, then the population will explode towards the upper equilibrium point at N_A . A subsequent crash is likely (the complications that make the dynamics of difference equations more unsteady than those of differential equations are discussed in the conclusion), with the population returning to the neighbourhood of N_B . The pest population may thus exhibit a periodic or episodic pattern of "outbreaks", followed by relatively long intervals at low densities.

Southwood⁴⁴⁻⁴⁶ has recently given a more quantitative discussion, and he and others have incorporated the practical conclusions into a morphology of strategies appropriate for the control of various kinds of insect pests⁴⁷⁻⁵⁰.

For example, Southwood and Comins⁴⁴ have interpreted Clark's thorough studies of the eucalyptus psyllid (a plant louse) *Cardiaspina albiteretura* in the light of Fig. 5. Using Clark's data for egg-to-adult survival for 29 generations, along with information about the depression of natality by direct crowding and by host plant deterioration, they estimate the shape of the $N(t+1)$ -versus- $N(t)$ curve. They find the curve to be of 'intermediate P ' type, and assign to N_B , N_C and N_A values corresponding to 2.8, 22 and 107 eggs per shoot, respectively. Not only does this give a qualitative explanation of the observed episodic outbreaks, but it is in remarkable quantitative agreement: Clark's field data give an average of 3.0 eggs per shoot at low densities, suggest a "rapid increase to outbreak level" beyond 10-15 e/s, and have a mean for 12 high density populations of 110 e/s (with a range 23-280).

Sufficient data have also been published on the European spruce sawfly, *Diprion hercyniae*, in New Brunswick for a tentative analysis of this kind. Southwood⁴⁷ suggests the present situation is one of 'intermediate P ', with the sawfly controlled by a com-

bination of virus disease and parasitoids: life-table estimates and field observations agree on a value of N_c around $0.2 \text{ larvae m}^{-2}$; fluctuations to higher densities result in runaway to around $N_A \sim 1 \text{ larvae m}^{-2}$, which is economically acceptable. Before the advent of the virus disease, the sawfly in New Brunswick seems to have been^{4,7} in a "low P " situation, with outbreaks to densities around 20 larvae m^{-2} followed by crashes.

Insect pests: the spruce budworm

One of the best studied of all insect pests is the spruce budworm, *Choristoneura fumiferana*, in Canada. This forest defoliator erupts at approximately 40-year intervals, causing much damage in northern coniferous forests, and economic stress in the lumber industry. The massive amount of data gathered by Morris⁵¹ and his associates has been subjected to much analysis by Holling and his collaborators^{15,52} (and D. Ludwig, D. Jones and C. S. Holling, to be published) at UBC and at the International Institute for Applied Systems Analysis (IIASA). One of the most pleasing features is the way the models have become progressively simpler as the basic mechanisms have become better understood. Thus the earlier 'systems models' have given way to Ludwig *et al.*'s⁵³ 3-component model (budworms; average leaf area per tree; energy reserve determining the condition of trees and foliage); the present review gives a crude 2-component model (budworms; leaf area) that retains the essentials.

Consider first the dynamics of the budworm population, $N(t)$. Yet again, this is plausibly described by Fig. 2 (with N replacing V), with the net population growth rate counterpoised between a natural growth term and losses due to predators. The general features described by Fig. 2 may be typified by the specific equation (3), which now reads

$$\frac{dN}{dt} = rN \left(1 - \frac{N}{K}\right) - \frac{\beta P N^2}{N_0^2 + N^2} \quad (5)$$

Here r is the intrinsic growth rate for budworms, and K is the carrying capacity, which depends on the average leaf area per tree, S ; we write $K = \kappa S$. N_0 is the characteristic budworm population at which the predator attack rate saturates (to the constant level β per predator). This characteristic value for predator switching will usually depend on budworm density per unit leaf area rather than on absolute budworm numbers, so that we may write $N_0 = \eta S$. Finally, for a given value of average leaf area S , it is convenient to use the rescaled variables $X = N/\kappa S$, $\tau = rt$ and $\gamma = \beta P/\kappa S$ to rewrite equation (5) in dimensionless form as

$$dX/d\tau = X(1-X) - \gamma X^2/(x^2 + X^2) \quad (6)$$

Here x is formally defined as $x = \eta/\kappa$, but biologically it retains the meaning it had in equations (2) and (4): for any given value of S , x is the ratio between the budworm density that saturates the predator attack capacity and the maximum budworm density that the vegetation can sustain. Equations (4) and (6) are identical.

As before, it is clear, either from the general Fig. 2 (which is drawn for small x) or from the specific equation (6) (provided $x < 1/3$, 3), that the budworm system may have two alternative stable states. If we fix the resource level S , and plot the stable budworm density N as a function of the number of predators P , we get exactly Fig. 3 (with N replacing V , and P replacing H).

It is more interesting, however, to fix the predator level P and consider how the equilibrium value(s) of N varies with S . This can be done graphically from Fig. 2, or algebraically from equation (5). The result is Fig. 6. A simpler way to arrive at Fig. 6 from Fig. 3 is to notice, from equation (6), that the equilibrium value(s) of N/S depends only on γ , once x is fixed. But $\gamma = \beta P/\kappa S$, so that S plays a part exactly like $1/P$: small P is equivalent to large S , and vice versa, whence Fig. 6 (with S for the x axis) follows from Fig. 3 (with P or H for the x axis). Moreover this makes biological sense. For budworms, the good life is few predators or lots of food; low P or high S . The bad life is the converse.

The main features of Fig. 6 need no elaboration. At low values of

S , there is a unique, and low, budworm density: the system is under predator control. At T_2 a second stable state appears discontinuously, and, for $T_2 < S < T_1$, N will tend to one or other of the two stable states, depending on which side of the 'breakpoint' locus it starts from. For S above T_1 there is again a unique stable state, in which the predators play little part.

This discussion of the budworm dynamics is not sufficient for a full elucidation of the way the interactive system of budworms and forest foliage behaves. We need also to consider how the average leaf area per tree, S , depends on N .

The essentials of such a discussion can be carried out⁵³, independent of any further details, by noting that the characteristic time scales for changes in N and in S are very different. The time scale for budworm population growth is months, or even weeks. The basic time scale for change in the average leaf area per tree depends on average branch area, and thence on the time scale for tree growth, which is typically measured in decades. Thus N changes on a relatively fast time scale, S on a slow one.

Fig. 6 The equilibrium budworm population, N , shown as a function of the average leaf area per tree, S . (This figure is based on equation (6), with $x = 0.06$.) The threshold and breakpoint features are similar to those in Fig. 3, and are discussed more fully in the text.

Returning to Fig. 6, we further suppose that budworm populations along the lower, 'predator-controlled' equilibrium curve do not have a significant impact on the foliage, so that S undergoes slow natural growth in this regime. Conversely, we assume that the large budworm populations along the upper equilibrium curve have a significant adverse effect on S , decreasing it. The qualitative nature of the system's dynamical behaviour now follows. Starting from any low values of N and S , the system will move rapidly (on the fast time scale) on to the lower budworm equilibrium curve in Fig. 6. S will now slowly increase, with N always quickly adjusted to the current S value, and the system will move (on the slow time scale) to the right along the lower equilibrium curve. When the system arrives at the point T_1 , no further continuous change is possible, and N jumps (on the fast time scale) to the upper equilibrium branch. Now S decreases because of the uncontrolled depredations of the budworms, and the system moves (fairly fast) to the left on the upper equilibrium curve. Finally, when the point T_2 is reached, N must fall (again on the fast time scale) back to the lower equilibrium branch, and the cycle begins again.

The upshot is a cyclic pattern of budworm explosions and crashes, as shown in Fig. 7. The system spends most of the cycle at low budworm densities, traversing the lower equilibrium curve from T_2 to T_1 . The cycle length is thus set by the slow time scale, and is of the order of decades.

A more explicitly mathematical treatment can be given crudely by assuming that the rate of change of S is given by a natural logistic growth term (with an intrinsic growth rate ρ), offset by

losses linearly proportional to the budworm density

$$dS/dt = \rho S(1 - S/S_{\max}) - \epsilon N. \quad (7)$$

Under the assumptions discussed above, the locus of equilibrium values of S (the points where $dS/dt = 0$) are as indicated by the dashed line in Fig. 7. The pair of equations (5) and (7) then lead to a stable limit cycle, as shown in Fig. 7. The limit $\rho \ll r$ corresponds to the foregoing distinction between slow and fast time scales, and leads to a limit cycle with the almost discontinuous character that was discussed above.

The work of Ludwig *et al.*⁵² is more detailed (involving three

Fig. 7 The (solid, $dN/dt = 0$) equilibrium curve for budworms, N , as a function of foliage, S , is as in Fig. 6. The (dashed, $dS/dt = 0$) equilibrium curve for S as a function of N has the form of equation (7). Under these circumstances, the system will settle to oscillate in a stable limit cycle, as indicated. The figure is for $\rho = 0.01r$, so that the budworm growth time scale is fast compared with the time scale for tree growth: as explained more fully in the text, this explains the main features of the cycle.

differential equations), and is compared with field data. They obtain numerical agreement with the observed 40-year cycle.

This model has implications for the management of budworm populations. Notice first that a program aimed at stopping budworm outbreaks has a propensity to hold the population perpetually poised on the brink of explosion, around the threshold point T_1 on the lower equilibrium curve in Fig. 6. More quantitatively, the effects of using insecticide against budworms can be mimicked by adding an extra mortality term, $-sN$, to the right hand side of equation (5). If we could maintain $s > r$ for many years, the budworms could in principle be eradicated. In the more likely event that $r > s$, the new version of equation (5) can again be brought into the dimensionless form of equation (6), with α replaced by $\alpha' = (r/r-s)\alpha$. We recall that the kinkiness in Figs 3, 4 and 6, and the ensuing alternative stable states, depends on α being small. Thus use of insecticides can increase the effective value of α to such an extent as to straighten out the kink in Fig. 6 (that is, can increase α' to a value $\alpha' > 1/3 \sqrt{3}$), leading to a unique stable state. The price, however, is daunting: not only are we committed to endless insecticide use, but the new equilibrium is necessarily established at a budworm density somewhere intermediate between the original upper and lower equilibrium levels. Such a budworm density represents a perpetual low-level outbreak.

It should be added that this discussion has ignored climatic fluctuations. One argument in favour of trying to 'hold the line' with insecticides is that one may thereby buy time, waiting for a year when unfavourable weather will carry the population back down to very low values.

Human host-parasite systems

Similar threshold and breakpoint phenomena occur in the transmission dynamics of many infections of humans and other

animals, particularly when the transmission cycle involves intermediate vectors.

Malaria is probably the best-known example exhibiting a threshold^{54,55}. Suppose that a single malarious mosquito is introduced into a closed and previously malaria-free community of people and mosquitoes. Each person bitten by this mosquito may, with a probability that can be estimated, become victim to the disease. These infected people may in turn be bitten by uninfected mosquitoes, which thereby (again with some probability factor, and after the elapse of a latent period of around 10 days) are recruited as malaria vectors. The key question is whether the original infectious mosquito produces, on the average, more than one subsequently infectious mosquito, or not. If it does, the system is 'above threshold', and the fraction of the human and of the mosquito populations that have malaria at any one time will grow until an equilibrium is reached, at which new infections are balanced against recoveries and deaths. Conversely, if it does not, the system is 'below threshold', and the introduced infection cannot be maintained.

This discussion makes clear the underlying nature of the threshold relation for malaria. The relation can be written explicitly in terms of the number of mosquitoes, biting rates, and recovery and death rates of mosquitoes and people; as reviewed by Macdonald^{54,55} and Conway⁵⁶, this threshold formula has many implications for management.

The main fact, however, is that for simple models of the malaria transmission process there is always a unique stable state: for mosquito densities above threshold, there is some endemic level of infection; below threshold the level is zero. For many helminthic infections the situation is made more complicated by the parasites' having a sexual stage in the human host. Thus, for example, an adult female schistosome will produce eggs only if she has a mate, which may be unlikely if the mean worm load per person is less than, or of the order of, unity.

Fig. 8 For a simple model of the transmission dynamics of schistosomiasis, the equilibrium mean worm load per person, m^* , is shown as a function of the snail population density (or other relevant transmission factor). The threshold and breakpoint phenomena are as discussed in the text. (From Bradley & May⁵⁹.)

As first stressed by Macdonald^{29,55}, the result is that for schistosomiasis and other parasitic infections with a sexual stage in the primary host there is, as before, a threshold transmission value which depends on the population density of the snails or other intermediate vector, on the rate of egg production in the primary host, and on other transmission parameters. Below threshold, there is only one equilibrium state, namely no infection. Above threshold, there are two alternative equilibrium states: if the initial mean worm load per person, m , is sufficiently high, the infection cycle is maintained; but if m is initially too small, the number of mated females (which will scale as m^2) may be insufficient for the system to 'take off' and attain its endemic equilibrium level. This situation is illustrated in Fig. 8, which corresponds to simple models for schistosomiasis^{29,56-58}. If the snail density (or other relevant transmission factor) is below the threshold value T , the

equilibrium level of adult schistosomes is zero. Above threshold, the mean worm load per person moves either to the upper equilibrium curve, or to zero, depending on whether its initial value lies above or below the "breakpoint" line.

Figure 8 is for a closed system, with no immigration of infectious snails or people from outside. If a small amount of such immigration is included (I. Nasell, to be published) the lower equilibrium curve in Fig. 8 must shift up to some small, but finite, level of infection, and a figure similar to Fig. 6 is obtained (with m replacing N , and snail density or the like replacing S).

The existence of a breakpoint holds important implications for control of the system^{29,55-59}. For diseases such as malaria, where there is always a unique equilibrium state, the only control strategy is to reduce the mosquito numbers and/or the biting rate and other parameters in such a combination as to take the system below threshold. The system must, moreover, subsequently be kept below threshold. But infections whose dynamics are as described by Fig. 8 can in principle be eradicated by temporarily displacing the mean parasite load below the breakpoint, thus taking advantage of the two alternative equilibrium states. This control strategy has the advantage that the basic transmission parameters do not have to be modified to, and maintained at, sub-threshold values. (If the infection dynamics of snails operates on a fast time scale, and of humans on a slow time scale, the locus of the breakpoint depends only on the level of infection among humans: more generally, the breakpoint will depend on both snail and human infection levels⁵⁶⁻⁵⁸. It also depends on whether the adult parasites are distributed among humans in random or clumped fashion^{58,59}.)

Current estimates are that about 200 million people have schistosomiasis, and about 300 million suffer from the various filarial infections (which include 'river blindness' and elephantiasis). But empirical information on the overall transmission dynamics of schistosomiasis and filariasis is scant, so that theoretical notions about threshold and breakpoints remain untested in this context.

Conclusion

This review has drawn together a variety of mathematical models for ecological systems, each of which is dealt with individually in the scattered literature. The models are united by the common theme of possessing a regime of dynamical behaviour in which there are two alternative stable states, so that continuous variation in a control variable can produce discontinuous effects. Thus smooth changes in stocking rates can cause discontinuous changes in the grazed vegetation; continuous changes in harvesting rates can cause discontinuous collapse in fisheries; continuous changes in environmental parameters or foliage growth or predation rates can lead to discontinuous outbreaks of insect pests; continuous changes in snail or dipteran population densities can cause discontinuous appearance or disappearance of helminthic infections.

These models can often be tied to empirical data, whence they yield specific insights into the management of the system. (Some of these insights can be recast in the language of catastrophe theory, but this is usually *post hoc* window-dressing. It is too often forgotten that catastrophe theory is, strictly speaking, a local theory; we want global descriptions of the dynamics.)

The review has been largely confined to the dynamical behaviour of a single population, albeit as a function of other populations of resources and predators. As the number of interacting dynamical variables, and of equations, increases things get more complicated. Consider, for example, a predator-prey system where the predator's dynamics depends on the prey population according to the backward-bending curve of Fig. 6 (N versus S), and where the prey's dynamics in turn depends on the predator population according to Fig. 3 (V versus H). These two curves—one for the predator equilibrium, the other for the prey equilibrium—are in principle capable of intersecting at 9 points, corresponding to no fewer than four alternative stable states (separated by four saddle points and one central hilltop), each with its own domain of attraction. As the dimensionality of the system increases to encompass more and more species, the dynamical

landscape can begin to look like the surface of the moon, and any detailed comparison with field or laboratory data becomes very difficult.

A different and additional complication is that systems with discrete generations are described by difference equations, which can exhibit kaleidoscopic dynamics. For such systems, of which Fig. 5 is an example, increasingly severe nonlinearities can make the dynamical behaviour range from a stable point, through a bifurcating hierarchy of stable cycles, into a regime which is in many ways indistinguishable from random noise⁶⁰⁻⁶². Similarly, patterns of stable points or cycles giving way to chaos can be found in systems described by differential equations with time lags, or even in simple first-order ordinary differential equations once 3 or more species are interacting^{60,62,63}.

These manifold complications can lead one to take a gloomy view of the possibility of making predictions about multi-species systems^{60,62}. The one kindly light amidst this encircling gloom is that many complex communities are, arguably, made up mainly of loosely coupled lower-order systems^{17,64,65}, to which the simple models reviewed here are pertinent.

Hypervelocity cratering and impact magnetisation of basalt

G. Martelli & G. Newton

Plasma and Space Physics Group, School of Mathematical and Physical Sciences, The University of Sussex, Brighton, Sussex, UK

Suitably modified explosive shaped charges have been used to produce small hypervelocity projectiles ($v \sim 15 \text{ km s}^{-1}$) to study e.m. effects associated with high-velocity cratering of basalts, thus simulating in a terrestrial environment some features of meteoritic impact on the lunar surface. The experiments have shown that plasma is formed during impact and that an external field can be impressed in the basalt.

IN an experiment to test whether meteoritic impact can magnetise lunar rocks (either by creating and impressing a transient magnetic field or by impressing and implanting a pre-existing field pattern), we made observations of magnetic phenomena associated with the cratering due to the impact of macroscopic ($m = 0.1\text{--}1 \text{ g}$) hypervelocity projectiles ($v \sim 15 \text{ km s}^{-1}$) on basalt blocks. For these experiments the 'meteoroid' consisted of the tip of the jet from a shaped charge and the target of a basalt block similar in composition to some lunar basalts. These tests were conducted in evacuated vessels, both with and without external magnetic fields either parallel or perpendicular to the basalt surface, and observations show that (1) a transient magnetic field followed by a short burst of electromagnetic oscillations is created near the impact region, and (2) it is possible to impress an externally applied magnetic field into the basalt.

Measurements of the magnetic field of lunar rocks have given values ranging between 10^{-2} and 1.2 Oe (refs 1, 2) for inducing fields necessary to account for the observed natural remanent magnetisation. Recent indirect observations from the Apollo 17 sub-satellite³ have confirmed the wide range of magnetic field intensities and orientations recorded by magnetometers flown on board previous Apollo missions.

Theoretical models based on lunar dynamo⁴ and fossil field theories^{5,6} have been invoked to explain the observations. Suggestions have also been made that there is evidence concerning the existence of a magnetic core⁷. Theories which can account, however, for both magnetic field amplification and/or local magnetisation mechanisms can explain more readily the wide range of observed values and are more amenable to direct experimental verification. Of these theoretical models, some assume the magnetisation to be associated with meteoritic impact⁸⁻¹⁰, while cometary impact has also been considered as a mechanism for impressing and magnifying an external magnetic field¹¹. Finally, during discussions with Professor K. Anderson, Space Science Laboratory, University of California, Berkeley in 1975 we considered the possibility that the plasma created during a hypervelocity impact could support transient electric

fields and associated electric currents, as observed in laser 'impact' experiments¹²⁻¹⁴. For hypervelocity impact, the residual magnetic field would be the remanent of an induced field, due to both the shock remanent magnetisation (SRM, or piezoremanence) and to the thermal remanent magnetisation (TRM) associated with the heating effects of the impact. The basic system of currents and inducing magnetic fields which can arise in laser 'impact' experiments, and can probably be present in hypervelocity impact experiments, are discussed in refs 15, 16 and illustrated in ref. 17 (see also for bibliography).

The only experimental technique we know of which has been used so far for the purpose of simulating shock compression associated with high-velocity impact is that of the explosively driven flying plate technique^{18,19} and interesting results have been achieved by this method²⁰. It differs, however, from the technique used here on a major point, since it does not actually simulate very closely the impact of a relatively small object on a large surface.

We describe here results from some experiments designed to simulate meteoritic impact, the 'meteoroid' consisting of the tip of the jet from a shaped charge, the target being a block of basalt with composition reasonably similar to that of some lunar basalt.

Experimental technique

Central to the experiments described below is the use of shaped charges to produce a high velocity jet of material, of which the

Fig. 1 Experimental set-up. L, Aluminium liner; D, deflector (TNT); E, explosive shaped charge (Octol); A, detonator; VT, vacuum tube; BD, blast deflector; T, target (basalt block).

Fig. 2. IRM field (continuous curve) and TRM field (broken curve) for basalt samples used in the experiment, *a*, SARM for a 10 G field perpendicular to the target surface; *b*, SARM for a 6 G field parallel to the target surface; *c*, SARM for the geomagnetic field parallel to the target surface.

tip only is allowed to impact on the basalt target; the remaining, and slower, portion of the jet is deflected by means of a subsequent explosion. As is well known, a metal lined shaped charge consists of a cylinder of explosive having a high detonation velocity (v_d), the cylinder having a metal lined conical cavity at one end. When detonated at the other end, the (plane) detonation wave implodes the cone and parts of it are ejected with a velocity larger than the detonation velocity (Monroe effect). The maximum velocity v_m depends on the opening angle α of the cone and the ratio of the mass of material that lags behind (the 'slug') is also a function of α . This ratio can be improved by truncating the cone at, say, about one tenth of its height, measured from the apex. The velocity gradient along the jet causes it to stretch and break up into individual pellets. We are interested in the fastest fragments of the jet, hereafter referred to as the 'tip'. If the density ρ_l of the liner is close to that of the explosive ρ_e , the shock impedance of the liner is well matched to the implosion wave, thus minimising surface reflection and maximising the amount of liner material in the tip. Provided the experiments are conducted in an evacuated system, the temperature of the jet is not expected to exceed a few hundred degrees Celsius, because of the cooling associated with the adiabatic expansion which it undergoes during flight.

In our experiments the liner was made of HE30 aluminium

alloy, which has a relatively low density ($\rho_e = 2.73 \text{ g cm}^{-3}$), is easily machinable and non-toxic. The explosive was Octol ($v_d \sim 8.4 \text{ km s}^{-1}$, $\rho_e \sim 1.8 \text{ g cm}^{-3}$). The angle α was 45° .

The experiment

The experimental set-up is illustrated schematically in Fig. 1. The system was evacuated by a rotary pump to $\sim 10^{-2}$ torr. On ignition of the explosive at A, the propagation of the detonation causes: (1) the explosive ejection of the tip of the jet, and (2) the shock ignition of the TNT deflector.

If the TNT deflector is properly placed, only the tip proceeds unperturbed while the remaining solid and gaseous debris is swept sideways. The best positioning of the deflector was obtained by trials against plates which recorded the impact. It was found that the debris could be deflected through $\sim 30^\circ$, and that only a small tip would reach the target.

The velocity of the tip was deduced by timing the flight over a set distance (1.5 m), the passage being recorded by the rupture of current carrying foils. Maximum values of v_m of $\sim 15 \text{ km s}^{-1}$ were recorded.

Fig. 3. A crater profile in a basalt block (shaded area). The field due to the SARM was measured 1.5 cm above the target surface, the magnetising field was $\sim 10 \text{ G}$ perpendicular to the target

We believe that the differences in magnetic structure between lunar and terrestrial basalts do not invalidate the aims of our experiments. We have, however, attempted to select basalt which minimises these differences. This was found at a quarry at Rowley Regis near Birmingham, which supplied us with approximately 30 t of selected blocks. The composition of the samples is given in Table 1.

Experimental results

Magnetic mapping of the surface of the basalt blocks before and after impact was carried out using both a Hall probe and a flux-gate magnetometer.

Before impact the field at the surface of the basalt blocks was found to be of the order of $10 \pm 10 \text{ mG}$.

The magnetic properties of the basalt have been measured using a large number of cores, up to 2.5 cm diameter, extracted from various blocks. Figure 2 shows the contribution to the measured field due to the isothermal remanent magnetisation at room temperature ('IRM', continuous curve) and to the thermal remanent magnetisation ('TRM', broken curve) obtained after heating the samples to about 800°C and letting them cool inside a solenoid. The largest contribution to the error comes from the spread of values obtained from different samples. The size of the cores was chosen so as to make the

Table 1 Composition of some Basalt samples from the quarry at Rowley Regis

	%
SiO ₂	50.17
Fe ₂ O ₃	4.61
Al ₂ O ₃	18.75
CaO	7.33
MnO	0.16
MgO	5.41
K, Na oxide	4.93
FeO	5.79
Others	2.86

The blocks were cut, faced and inspected for homogeneity and absence of microfractures. The selected blocks were individually encased in alumina cement inside a reinforced dural frame, $45 \text{ cm} \times 45 \text{ cm} \times 25 \text{ cm}$, to prevent rupturing during test. The experiments were carried out in a reinforced concrete bunker at one of the proving grounds of the Raufoss Ammunition Factory, near Oslo.

field measurements practically independent of the core size, thus enabling the measurements to be compared directly with those at the surface of the basalt blocks.

We emphasise that, because of the short duration of the impact process, it is not possible to differentiate reliably between thermal remanent magnetisation and piezoremanent effects, so, hereafter, we refer to the magnetisation associated with the impact as 'shock associated remanent magnetisation' (SARM).

Three main types of hypervelocity impact tests were performed, and we present data from one of each. (1) with a 10 Oe external magnetic field at right angles to the basalt surface; (2) with a 6 Oe field parallel to the basalt surface;

conducted successfully in an evacuated vessel without an externally applied magnetic field, revealed magnetic perturbations at the basalt surface reaching up to ~ 40 mG near the crater (see inset in Fig. 2 marked 'c'). This value is no more than three to four times larger than the fluctuations recorded across the surface before impact. It may be that since the impact created a crater larger than was the case in the other tests, any more strongly magnetised material in the neighbourhood of the impact area may have been lost with the ejecta.

In some of the experiments mentioned above we recorded the electromagnetic noise generated on impact, using pickup coils surrounding the glass tube near the basalt surface and a 20-kHz bandwidth instrumentation recorder. In all cases we observed a rapid (probably bandwidth limited) transient magnetic field during impact followed by a number of oscillations (Fig. 4a). This suggests the creation of plasma capable of sustaining azimuthal currents, and possibly, transient flute instabilities. If this interpretation is correct, the current can be estimated from the amplitude of the recorded signals, to be of the order of 10^{-1} A. A similar experiment performed using the same geometry but at atmospheric pressure showed a faster transient magnetic field but much less pronounced oscillations (Fig. 4b). The question of how much plasma is formed on impact, at what temperature, and the type of transient instabilities generated therein needs further investigation.

Conclusions

Our experiments indicate that: (1) plasma is created by hypervelocity impact of small projectiles on a basalt surface; (2) an external magnetic field is impressed during impact, the SARM value being of the order of, or slightly exceeding that, of the TRM of samples of the same basalt. However, when the external field is as low as the geomagnetic field, the observed SARM is substantially larger than the corresponding TRM. (3) By extrapolating this result to impacts occurring in a field free region, it would seem that a magnetic perturbation can be created by the impact and impressed in the basalt. This point, however, requires further detailed measurements in a field-free environment.

We thank the Raufoss Ammunisjonsfabriker AS for hospitality and support and, in particular, the help of the Chief Engineer E. Myrvold, and Dr E. Trøen. We thank Professor R. Hide, of the Meteorological Office, Bracknell, UK, Dr L. J. Srnka, of the Lunar Science Institute, Houston, Texas, USA, and Mr J. Dangerfield, Institute of Geological Sciences, London, UK for discussions. The Turners Hill quarry at Rowley Regis provided the basalt blocks free of charge. We also thank Mr F. Schofield of Sussex University for building most of the experimental apparatus and Mr O. P. Solberg, Mr B. Blackman for assisting during the tests.

Fig. 4 Pickup signals from a coil surrounding the impact area. *a*, The vessel evacuated to 10^{-2} torr; *b*, in air. Note the different time scales.

(3) in the ambient magnetic field which, inside the bunker, was 0.5 G in the vertical direction.

The results of each of these tests are as follows:

Test type (a). Magnetic field measurements of the impact area yielded profiles such as that shown in Fig. 3. It can be seen that the largest SARM values are found in the neighbourhood of the field after impact is parallel to that of the externally applied field. The extreme values of the measured field due to SARM effects in the neighbourhood of the crater are shown in Fig. 2, as the error box marked 'a'.

Test type (b). In the region neighbouring the crater, relatively large magnetic fields were detected (approximately 100 mG). The maximum perturbations seem to be concentrated near the crater rim, along the fracture lines, that is, where the shock reached probably its highest value. The extreme values of the measured magnetic field for this test is also shown in Fig. 2, and is marked 'b'.

Test type (c). The results of the only impact experiment

Thermodynamic theory of size dependence of melting temperature in metals

P. R. Couchman* & W. A. Jesser

School of Engineering and Applied Science, Department of Materials Science, University of Virginia, Charlottesville, Virginia 22901

The way that small particles melt is a crucial element in the construction of a thermodynamic treatment of the relation between particle size and melting temperature. There are indications that melting is initiated at the surface and that the solid-liquid interface sweeps rapidly through the solid at the melting temperature. The formal and physical elements of the indicated nucleation and growth criterion for melting are discussed and the existence of upper and lower limits on the melting temperature is outlined. Theoretical predictions show satisfactory agreement with experimental observations.

THE effect of particle size on melting temperature has promoted explicit theoretical discussions since the early 1900s and extensive experimental investigations have been reported. The qualitative experimental features are fairly simple—a monotonic decrease in melting temperature with decreasing particle size^{2–16}, this variation seems to be more substantial in the lower end of the size spectrum than in the 'large' size regime^{5–13, 15, 16}.

Previous theories have considered the solid-liquid-vapour mutual equilibrium¹⁷ (actually a size-dependent triple point^{18–20}) as the chemical equilibrium condition for a solid sphere embedded in bulk liquid¹⁸ (this, however, is related to the classical supercooling problem rather than to the melting of small particles), chemical equilibrium between solid and liquid spheres of identical radius¹⁹. In a later theory the 'thermodynamic melting temperature' was defined as that of Pawlow¹⁷ (although this is not necessarily the actual transformation temperature)²¹. Several of these and other works^{4–10, 19} have considered solid-liquid contact to be a central point: the favoured liquid skin theory considers chemical equilibrium between a finite liquid layer and the surrounded solid at the melting temperature^{4, 5, 7, 9}. Unfortunately, no physical criterion has emerged by which to determine the liquid thickness; this quantity (assumed constant) and the solid-liquid interfacial tension are determined by fitting the theoretical expression to experimental results.

In view of these problems associated with previous treatments of the size-dependence of melting temperature we have reconsidered the problem, and we present a thermodynamic theory of the relation between particle size and melting temperature.

Size dependence of melting temperature

Unlike in bulk systems, in small particles the mode of melting is a crucial element for the construction of a thermodynamic theory of melting. The size-dependence of intensive parameters in these systems requires that the geometry and extent of both phases be determined at the melting temperature. Consequently, it is imperative to consider the question of the mechanism of melting in general, and of small particles in particular.

First, note the essential asymmetry between melting and freezing—substantial liquid supercoolings are normal, whereas there is no significant superheating in solids. There is evidence that this lack of superheating is a surface-related effect^{22–24}; additional support for the important role of the surface in initiating melting is provided by kinetic studies of superheating^{25, 26}, low-energy

electron diffraction (LEED) studies of surface melting and freezing of (Pb, Bi and Sn) single crystal surfaces²⁷ and neutron scattering experiments indicating the absence of any bulk phenomena associated with melting in Al to within 10^{-1} K of the melting temperature²⁸. Moreover, molecular dynamics simulations of melting in small clusters of (rare gas) atoms indicate quite unambiguously that the transition is initiated at the surface^{29–31}. Finally, the fact that liquid metals wet the parent solid, energetically favours the initiation of melting at the surface²³.

Evidently, at the melting temperature a liquid layer is formed on the surface and moves at a substantial rate into the solid. It is these nucleation and growth characteristics of the melting phenomenon that may be used to construct a thermodynamic theory of the size-dependence of melting temperature.

The (closed, constant total volume) system considered is an isolated one-component collection of non-contiguous metal spheres at a uniform temperature and individually in mechanical equilibrium, resting on a non-interacting substrate. There are no dissociated species, no evaporation occurs during melting and gravitational effects are assumed negligible. Additionally, the difference between surface stress and surface free energy per unit area³² is neglected.

It is useful to recognise that a size-dependent absolute lower limit on the melting temperature exists. Neglecting the small vapour free-energy change this temperature, T_{lb} , is defined by the condition that the Helmholtz free energy difference between the final, entirely liquid, and initial, entirely solid, particles vanishes. The Helmholtz potential is appropriate as there is a pressure discontinuity associated with the melting of small particles. In equation (1) the subscripts s and l refer to solid and liquid; σ , areal surface work; r , particle radius; v , atomic volume; T_0 , bulk melting temperature; and l_0 latent heat, whence neglecting all but first order terms

$$T_{lb} = T_0 \left\{ 1 - \frac{3}{l_0} \left[\frac{r_s \sigma_s}{r_s} - \frac{r_l \sigma_l}{r_l} \right] \right\} \quad (1)$$

Although T_{lb} has been discussed as the two-state melting temperature^{7, 9, 34} it cannot be the actual melting temperature unless the mechanism by which the final state is attained is irrelevant (that is, in the limit of vanishing particle size).

The melting mode, and consequently the actual melting temperature, involves the formation of a liquid layer and a criterion to determine its spontaneous growth to consume the solid. The derivation and formal analysis of the Helmholtz free energy difference ΔF_i between a core of solid surrounded by a concentric liquid layer and an entirely solid particle is thus complemented by the development of a melting criterion; their combined use leads directly to a quantitative estimate of the relation between particle size and melting temperature and, finally, to a comparison with experimental results. For brevity and simplicity we reproduce the principal features of the results of this energetic analysis by considering (where appropriate) only first-order terms. The superscript prime denotes quantities of the combined (solid-liquid) system. Those of the entirely solid system have no superscript. Pressure, temperature, chemical potential, number of atoms, volume and area are respectively, P , T , μ , N , V , A . The double subscript sl denotes quantities of the solid-liquid interface. Matter conservation is assumed between the solid and liquid states. Formally, ΔF_i is given by

*Present address: Materials Research Laboratory and Polymer Science and Engineering Department, University of Massachusetts, Amherst, Massachusetts 01002.

$$\Delta F_i = -P_s'V_s' + P_l'V_l' - P_i'V_i' + (\mu_s' - \mu_s)N_s' + (\mu_s' - \mu_s)N_l' + \sigma_{sl}A_{sl} + \sigma_l A_l - \sigma_s A_s \quad (2)$$

Explicit integration of the relevant Gibbs–Duhem relations provides a lengthy and analytically intractable expression for ΔF_i (ref. 1). Fortunately there are two simplifying approximations which retain all essential physical insight of the problem and provide an expression amenable to formal qualitative investigation: the liquid and solid atomic volumes are taken to be identical ($v_s = v_l \equiv v$) and both of these phases are assumed incompressible. These approximations yield the following expression

$$\Delta F_i = \frac{l_0(T_0 - T)}{T_0} \times \frac{4\pi}{3} \frac{r^3 - (r-t)^3}{v} + \sigma_{sl}4\pi(r-t)^2 + (\sigma_l - \sigma_s)4\pi r^2 \quad (3)$$

where r denotes the initial solid (and here, final liquid) radius and t the liquid thickness. This function may be shown to have a stationary value (σ_{sl} , σ_l and σ_s are here approximated as size-independent) with respect to t (or, here, N_l) at constant temperature, when

$$\frac{l_0(T_0 - T)}{T_0} = \frac{2\sigma_{sl}v}{(r-t)} \quad (4)$$

This is simply the condition that the solid core has the same chemical potential as the surrounding liquid layer. For $\sigma_{sl} < 0$, physical solutions of this relation demand that $t > r$ and $T > T_0$. The extremum of equation (4) is then a maximum

$$\frac{1}{8\pi} \left(\frac{\partial^2 \Delta F_i}{\partial t^2} \right)_T = -\sigma_{sl} \quad (5)$$

and thus, equation (4) defines an unstable chemical equilibrium. An approximate upper limit, T_{ub} , on the melting temperature may be inferred from the condition $\delta \Delta F_i / \delta N_l|_T > 0$ for vanishing t

$$T_{ub} = T_0 \left(1 + \frac{2\sigma_{sl}v}{l_0 r} \right) \quad (6)$$

Below T_0 the transformation of solid to liquid is favoured by the surface term (due to the wetting condition) and retarded due to the volume (latent heat) term. This is the converse of the classical nucleation problem and is consistent with the surface-induced nature of melting³⁵.

If the non-wetting condition $\sigma_s > \sigma_l + \sigma_{sl}$ is obeyed, the possibility of superheating exists; the condition $T < T_0$ restores the latent heat as the driving force for melting. It seems that a theory of the size-dependence of solid superheating analogous to the melting theory is possible. This explanation and such a theory relate to Peppiatt's experiments²².

The Helmholtz free energy difference, ΔF_i , required to form a liquid layer on and from the completely solid particle is a maximum at the critical liquid thickness, t_c , defined by equation (4). In nucleation theory the probability of attaining this critical fluctuation will determine the speed of movement of the solid–liquid interface into the solid. A formal relation between temperature, the critical Helmholtz energy fluctuation ΔF_c and a measure, J , of this rate of movement is given by

$$J = C \exp[-\Delta F/kT] \quad (7)$$

where the pre-exponential factor C is only mildly temperature dependent and is taken as constant³⁵ and equal to that calculated by Stowell³⁶. The critical melting fluctuation ΔF_c is formally given here by equation (3) evaluated at the chemical potential equality condition of equation (4). The various dependences (calculated, estimated or measured) of quantities needed to determine correction terms to the first-order expression quoted here are discussed in detail elsewhere¹.

Comparison of theory with experiment

A comparison of the predictions of this theory with experimental results is given in Figs 1–3. Sn, In and Au were chosen because these

Fig. 1 Relation between melting temperature (T_m) and reciprocal particle radius (r^{-1}) for tin. —, Calculated; O, experimental. The latter were obtained directly or by interpolation from Wronski⁵ and are (except at $r^{-1} = 0.025 \text{ Å}^{-1}$) midway between the experimental scatter. The scatter increases as particle size decreases and consequently is largest (and mostly unavoidable) at smallest r . At $r^{-1} = 0.025 \text{ Å}^{-1}$ the apparent upper and lower values of T_m are illustrated. The solid curve represents the results of the calculation using equations (3, 4 and 7).

Fig. 2 Relation between melting temperature (T_m) and reciprocal particle radius (r^{-1}) for indium. —, Calculated; O, experimental (Pöcza, Barna and Barna¹³); Δ, (Berman and Curzon¹¹). The points are taken directly from Pöcza *et al.* and directly or by interpolation from Berman and Curzon. The scatter in the small size regime is illustrated for Berman and Curzon's data; the error bars reported by Pöcza *et al.* for small r are likewise given. The solid curve represents the results of the calculation using equations (3, 4 and 7).

Fig. 3 Relation between melting temperature (T_m) and reciprocal particle radius (r^{-1}) for gold. —, Calculated; Δ , experimental (Sambles¹⁰); \circ , (Buffat and Borel¹⁶). Data obtained and treated as for Fig. 1.

were the only metals with both a sufficient number of surface parameters available (latent heats and heat capacities are relatively well documented) to allow theoretical calculations and a sufficient number of experimental results to allow a significant comparison between theory and experiment. The qualitative agreement is good. Further, the quantitative agreement is satisfactory in view of the approximations involved in the theory, the known lack of precision (and accuracy) in some of the quantities and their variation and the difficulty in obtaining accurate melting temperature and size measurements over such a large range. Actually, the only surface parameter we used which had any substantial experimental disagreement is σ_{sl} . We have used values consistent with the strong evidence that its direct determination from grain boundary grooving measurements³⁷ yields a significantly larger value than that inferred from supercooling measurements—the latter give a lower limit to σ_{sl} .

These calculations indicate that the critical liquid thickness (t_c) is not constant for each metal^{4,5,7,9} but decreases monotonically with decreasing particle size.

Conclusion

The thermodynamic theory of the size-dependence of melting temperature outlined here seems to provide a satisfactory and physically acceptable explanation of the phenomenon and is in reasonable agreement with experimental observations. Although other treatments have implied that solid-liquid interface movement is important in the transition^{4-9,15,19} (Tammann³⁸ was the first to suggest that melting is a surface phenomenon) none has sought to explore the surface nucleation and liquid layer growth characteristics of melting in order to provide a formal treatment of the size-dependence of melting temperature.

One expected and important feature of melting in small systems that this treatment predicts is the 'smearing out' of the transition as particle size decreases. This effect stems from the basic (nucleation and growth) characteristics of the melting phenomenon although its predicted extent is minimal; and the transition is predicted as extremely sharp down to very small particle size. (< 1 K even at the small end of the size spectrum.)

Corrected age of the Pliocene/Pleistocene boundary

Bilal U. Haq & W. A. Berggren

John A. Van Couvering

University of Colorado Museum, Boulder, Colorado 80302

Calcareous plankton datum-events are referred to the Pliocene/Pleistocene boundary at Le Castella, the stratotype Calabrian at Santa Maria di Catanzaro, and to deep-sea sediments in six piston cores. The boundary is correlated by multiple overlapping criteria to a level equivalent to, or slightly younger than, the top of the Olduvai Event, giving a revised estimate of about 1.6 Myr for the age of the boundary. The Pliocene/Pleistocene boundary is thus coeval with the earliest of four major climatic deteriorations in the Pleistocene, reconciling palaeoclimatic concepts with the chronostratigraphical definition of the epoch.

ESTIMATES of the age of the Pliocene/Pleistocene boundary have varied from about 0.6 Myr¹ to > 4 Myr^{2,3}. The absence of reliable palaeomagnetic measurements on the stratotype of the Calabrian at Santa Maria di Catanzaro⁴ and the boundary-stratotype section at Le Castella^{5,6} in southern Italy has prevented direct correlation with the palaeomagnetic polarity 'scale'. Over the last decade biostratigraphical studies on the critical sections in southern Italy and also on palaeomagnetically-dated deep-sea cores have resulted in essentially two estimates for the age of the boundary: 1.6–1.8 Myr, by association with the Olduvai Event^{7–11} and 2.8 Myr, by association with the Kaena Event^{4,12–14}. Those who agree with the younger date have generally believed that the base of the Calabrian, as defined at Santa Maria di Catanzaro¹⁵, was stratigraphically equivalent to the 'marker-bed' at Le Castella¹⁶; these workers have

referred to the Le Castella 'marker-bed' section as the reference section for dating the age of the boundary. On the other hand, those who agree with the older date have consistently referred the boundary to a level near the physical base of the Catanzaro section. This level, the approximate transition from Pliocene clays to sandier beds above that indicate a different environment—the so-called Sandy Calabrian—is more than 75 m below the level of the prominent sandy calcarenite, Bed G-G' of Gignoux's defining study, which was the designated base of the Calabrian Stage originally and which is now placed at the base of the Calabrian stratotype^{17,18}.

We present here the results of a study of the calcareous plankton

(first appearance datum) of the members of the coccolithophore genus *Gephyrocapsa* in four of the palaeomagnetically-dated deep-sea cores (Fig. 1) and at Le Castella (Fig. 2). The minute size of the specimens (commonly 1.5–7 µm) and the subtlety of the criteria that distinguish various *gephyrocapsid* taxa, makes species differentiation (except the end members of the lineage, *G. aperta* and *G. oceanica*) under light microscope at best unreliable. Scanning electron microscopy, as used in this study, is essential (Fig. 4).

In core V12-18 *G. aperta*, the earliest (Fig. 1) and morphologically simplest form (Fig. 4a), appears at about 2.25 Myr. More evolved forms, such as *G. protohuxleyi* and *G. omega*, appear within the Olduvai Event in cores CH61-171 and V12-18,

Fig. 1 Biostratigraphy of piston-core samples, showing ranges of taxa that are critical to the correlation of the Pliocene/Pleistocene boundary as related to normal-polarity Olduvai Event (hatched interval). Ranges are shown according to observations made in this study; previously published observations of range-limits in these cores are indicated by numbered points, as follows. (1), Bielak and Briskin⁴⁰; (2), Gartner⁴¹; (3), Saito *et al.*¹¹; (4), Briskin and Berggren³⁷. Location of the various cores is: RC11-220: 14° 49'S, 139° 58'W; V28-239: 03° 15'N, 159° 11'E; V24-59: 02° 34'N, 145° 32'W; CH61-171: 26° 41.5'N, 39° 23'W; V16-205: 15° 24'N, 43° 24'W; V12-18: 28° 41.7'S, 34° 29.6'W.

of six palaeomagnetically-dated deep-sea cores, and of the Calabrian sections of southern Italy. We have established a calcareous plankton biochronology in the deep sea cores that is applicable to these sections and which provides a more accurate means of estimating the age of the Pliocene/Pleistocene boundary than has previously been possible. We use the geomagnetic polarity scale of Cox¹⁹, consider the Gilsa and Olduvai events to be age equivalent²⁰, and assign ages of 1.61–1.79 Myr to the upper and lower limits of the Olduvai Event, respectively.

Material

We have examined, or reviewed literature on, calcareous plankton microfossils from six palaeomagnetically-dated deep-sea cores (Fig. 1). Planktonic foraminifera from core V16-205 were examined by W.A.B. for another study so that two sets of observations are shown for that core. Calcareous nannoplankton are selectively dissolved and fragmented over the interval of the Olduvai in V28-239, but the remaining biostratigraphical data on the cores is shown in Fig. 1. By way of comparison, calcareous nannoplankton and selected foraminifera have been examined in 60 samples from the stratigraphical section at Le Castella (Fig. 2) and samples from Santa Maria di Catanzaro (Fig. 3) which were collected by F. Barbieri in 1971.

Calcareous nannoplankton

The basic biochronological framework for correlating the Pliocene/Pleistocene boundary is provided by the sequential FAD

respectively. In four cores (CH61-171 and V16-205 from the South Central North Atlantic; V12-18 from the western South Atlantic; and RC11-220 from the South-East Equatorial Pacific) the upper boundary of the Olduvai is straddled by the FAD of *G. caribbeana* (below) and *G. oceanica* (above). Mean ages of 1.62 Myr and 1.57 Myr respectively are assigned to these FAD events.

In the relatively long South Atlantic core V12-18, it has also been possible to assign ages to the LAD (last appearance datum) of the last four remaining discoasters of late Pliocene age. *Discoaster surculus*, *D. asymmetricus* and *D. pentaladialis* disappear sequentially around 2.3 Myr, just before the FAD of *G. aperta* (Fig. 1). The terminal discoaster, *D. brouweri*, disappears within the Olduvai Event, but apparently slightly earlier (that is, near the base of the Olduvai, ~1.8 Myr) in the South Atlantic core V12-18 than in the Central North Atlantic (CH61-171, V16-205), or Equatorial Pacific (RC11-220, V24-59) where it disappears close to the top of the Olduvai Event, ~1.64 Myr. Specimens occur rarely and sporadically above this level in some cores. Considering the ease with which calcareous nannoplankton can be reworked into younger strata, the *D. brouweri* LAD as shown in cores CH61-171, V16-205, and RC11-220 may be slightly younger than the actual extinction level of this species. A three-rayed variety of this species becomes more numerous near the LAD in many cores.

The sequence of evolutionary events in the *Gephyrocapsa* lineage seen in the deep sea cores also occurs in the Le Castella section (Fig. 2). We have examined in detail 60 nannoplankton samples from this section under both light and scanning electron

microscopes. *Gephyrocapsa aperta* is found in sample CAT 3, some 105 m below the boundary marker bed. *G. protohuxleyi* is found in sample CAT 14, about 40 m below the marker-bed and morphologically typical *G. caribbeana* (that is, comparable with the holotype) and *G. oceanica* are found in samples CAT 34 and CAT 36, ~30 and 25 m below the marker-bed, respectively. Throughout the Le Castella section, reworked discoasters of early and late Tertiary age are found. But, some 50 m below the marker-bed, *D. brouweri*, the terminal representative of the genus, decreases abruptly in abundance; approaching this level from below, it occurs relatively numerous and continuously and the three-rayed variety grows relatively more numerous. Above this level, however, it occurs relatively rarely and sporadically and about 15 m below the marker-bed it virtually disappears. This distribution pattern of *D. brouweri* has been observed previously²¹, and we consider the true LAD of *D. brouweri* to be ~50 m below the marker-bed.

Planktonic foraminifera

In the same samples, a series of planktonic foraminiferal datum levels are also associated with the early Matuyama Epoch, and the Olduvai Event in particular⁹⁻¹¹.

In the subtropical South (V12-18) and North (V16-205) Atlantic the LAD's of *Globorotalia miocenica* and *Globorotalia exilis* fall within the interval of 2.2 to 2.0 Myr, slightly below the Olduvai Event. The FAD of *Globorotalia truncatulinoides* is associated with the base of the Olduvai Event, occurring some 10-20 cm below it in Equatorial Pacific core V28-239, and

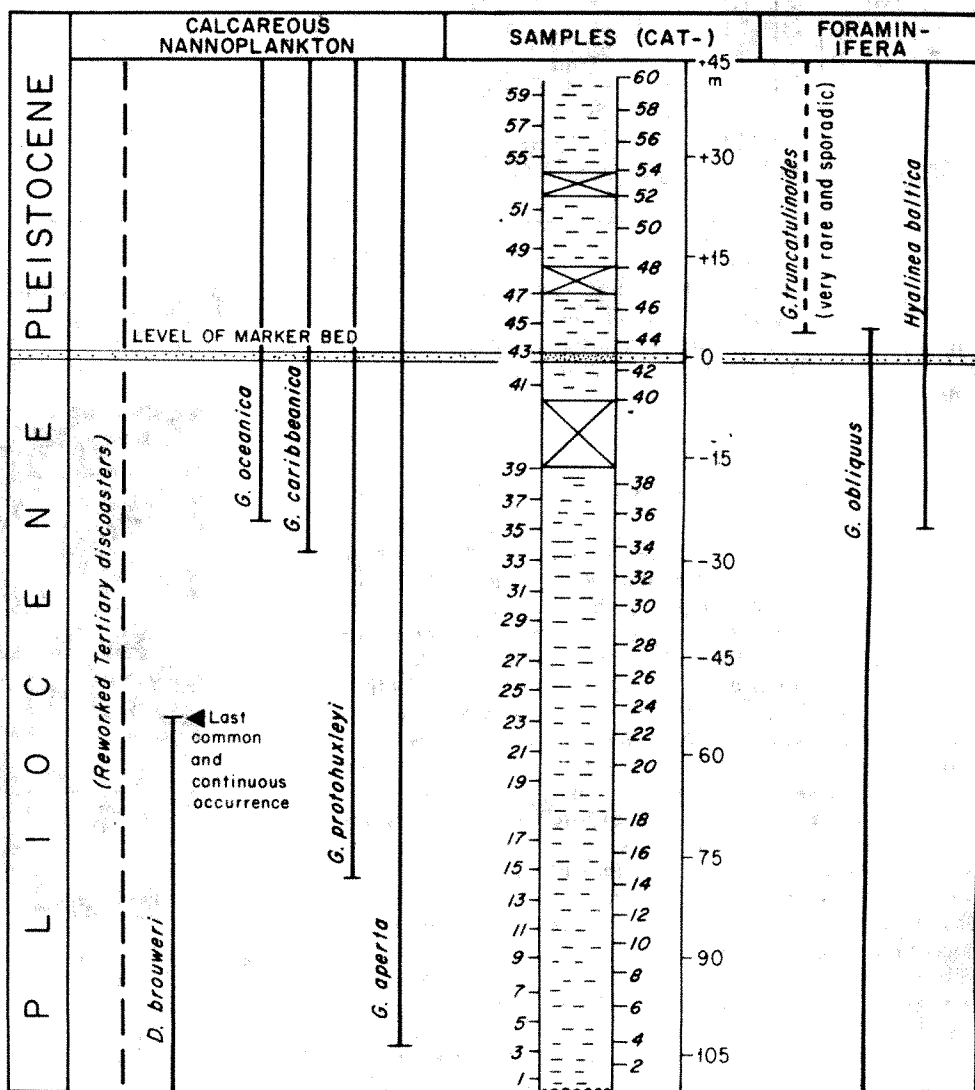

10-20 cm above it in subtropical North Atlantic cores V16-205 and CH61-171. The LAD of *Globigerinoides obliquus* is virtually coincidental with the top of the Olduvai Event in V16-205 and V12-18 (Fig. 1) and with the marker bed at Le Castella (Fig. 2). The LAD of *Globigerinoides fistulosus* also seems to be close to the top of the Olduvai Event (mid-part of Olduvai in V12-18; coincident with the top in V24-59 and slightly above it in V28-239). An anomalously young (~1.3 Myr) LAD of this species is noted in RC11-220.

The lowest recorded occurrence of *Globorotalia truncatulinoides* at Le Castella is ~2 m above the Pliocene/Pleistocene boundary (Fig. 2) and at Santa Maria di Catanzaro ~30-40 m below Bed G-G' (Fig. 3). Various other levels for this first occurrence have been cited^{1,6,16,22,23} but this unreliability seems to be due primarily to the extreme rarity of specimens.

Benthonic foraminifera

The calcareous benthonic foraminifer *Hyalinea baltica* is generally regarded as one of the primary biostratigraphical criteria for the base of the Pleistocene in the Mediterranean²². At Le Castella the FAD of this taxon is generally regarded as coincident with the lithostratigraphical marker-bed (between samples CAT 50 and 51) separating Pliocene and Pleistocene¹⁶. But, the range of *H. baltica* has been found²⁴ to extend at least 25 m below the marker-bed, at which level it constitutes 17% of the total benthonic fauna. At Santa Maria di Catanzaro *H. baltica* occurs near the base of the exposed section, at least 65 m below Bed G-G' (Fig. 4). If the FAD of this taxon was approximately simultaneous within the basin in

Fig. 2 Stratigraphical occurrence of calcareous plankton taxa and *Hyalinea baltica* at Le Castella (Calabria, Italy). Samples (CAT), collected by F. Barbieri in 1971, are the same as those studied by Rio²⁵.

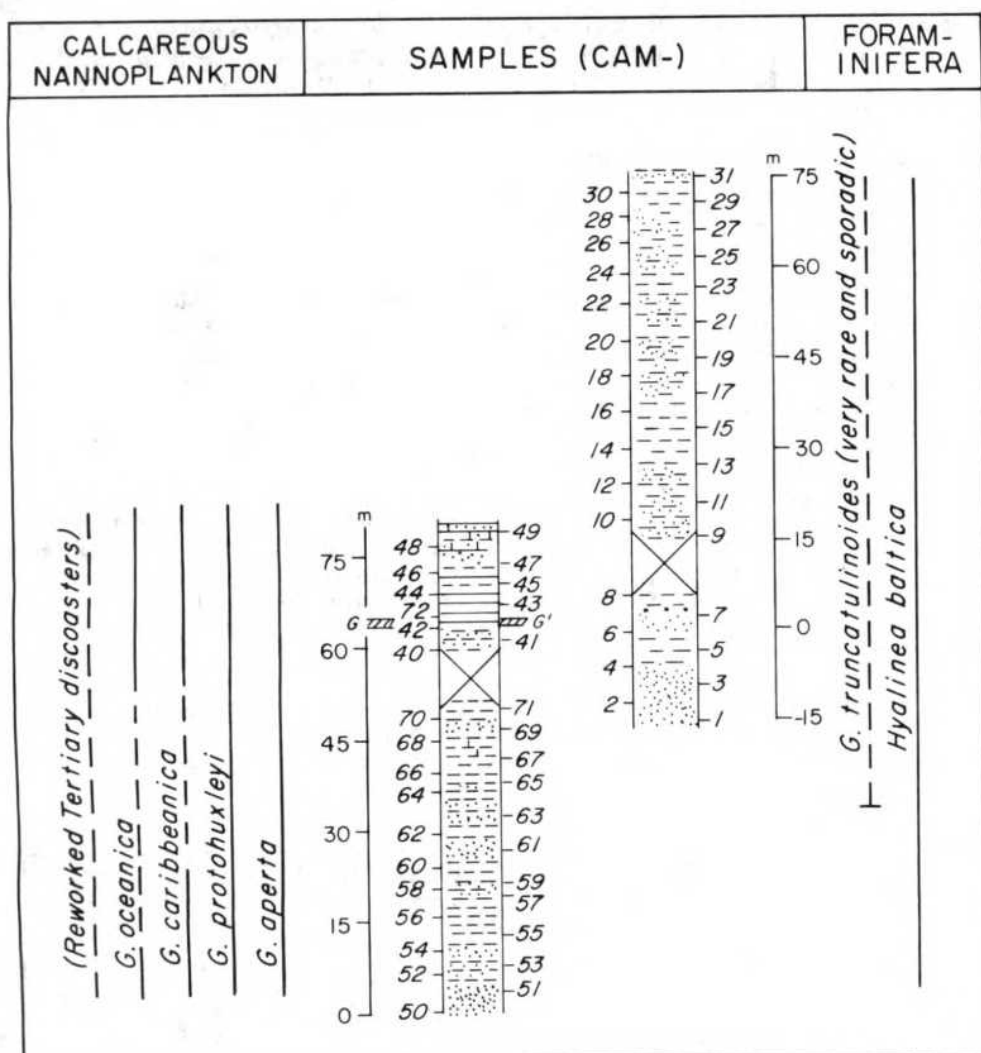

Fig. 3 Stratigraphical occurrence of calcareous plankton and *Hyalinea baltica* at Santa Maria di Catanzaro (Calabria, Italy). Samples (CAM), collected by F. Barbieri in 1971, are the same as those studied by Rio²⁵.

which these two sections are located, it would suggest that the marker bed at Le Castella is significantly older than Bed G-G' at Santa Maria di Catanzaro. This is, in fact, the conclusion that we have reached from the comparison of calcareous plankton datum events.

Age of Pliocene/Pleistocene boundary

If we apply the calcareous nannoplankton biochronological framework established from deep-sea cores (LAD of discoasters at 1.65 Myr and FAD of *Gephyrocapsa caribbeanica* and *Gephyrocapsa oceanica* at 1.60 Myr; Fig. 1) to the Le Castella section and assume a relatively constant rate of sedimentation, a minimum age of ~1.55 Myr is derived for the level of the marker bed denoting the Pliocene/Pleistocene boundary. A similar conclusion with a 1.4-Myr estimate for this boundary was published by D. Rio²⁵. But, the association of the *Globigerinoides obliquus* LAD with the top of the Olduvai Event in deep-sea cores and with the marker-bed at Le Castella suggests an age closer to 1.6 Myr for the boundary level. The upper bathyal clays of the Le Castella section are known to include (at least minor amounts of) clastic turbidites that contain displaced shallow-water benthonic foraminifera. A uniform sedimentation rate therefore cannot be assumed, and in view of these uncertainties we suggest a mean age of 1.6 Myr for the Pliocene/Pleistocene boundary at Le Castella.

There are two lithostratigraphical levels which are cited as definitive for the conceptual basis of the Pliocene/Pleistocene boundary: (1) Bed G-G', at Santa Maria di Catanzaro, a prominent calcarenitic lens (of turbidite origin) which contains abundant fossils of the shallow-water mollusc *Arctica islandica*

and is generally considered to define the lithostratigraphical base of the Calabrian Stage^{17,18}; (2) the indurated (turbiditic) sand layer at Le Castella (between samples CAT 50 and 51) and which has been generally considered as the boundary-stratotype of the

Fig. 4 Scanning electron micrographs of important gephyrocapsid species used in the biochronology of the Pliocene/Pleistocene boundary interval: a, *Gephyrocapsa aperta* Kamptner, Core CH61-171, 431 cm; b, *G. protohuxleyi* McIntyre, Santa Maria di Catanzaro Section, CAM-1; c, *G. caribbeanica* Boudreaux and Hay, Core V12-18, 709 cm; d, *G. oceanica* Kamptner, Core CH61-171, 431 cm. $\times 10,000$.

Pliocene/Pleistocene^{16,26}. Correlation between the stratigraphic sections and the age of the boundary markers at Le Castella and Santa Maria di Catanzaro has caused much controversy. Orthodox opinion has been that the two marker-beds are stratigraphically equivalent^{16,22} and that the boundary is about 1.8 Myr^{10,11,27}. One strongly dissenting opinion^{12-14,28} has been that the true base of the Calabrian, and the Pliocene/Pleistocene boundary, is represented by the base of sandy Calabrian beds that extend more than 75 m stratigraphically below Bed G-G' at Santa Maria di Catanzaro, and that this level should be dated at about 2.8 Myr. In this view, the marker bed at Le Castella is about 1 Myr younger, and represents the base of the Emilian Stage. In contrast, another dissenting opinion²⁹⁻³¹ holds that the lowermost Calabrian—equivalent to the Le Castella section—is missing at Santa Maria di Catanzaro because the sandy Calabrian is transgressively unconformable on the clayey Pliocene beds, and as a consequence all of the Calabrian (*s.l.*) above this contact is younger than the Le Castella marker-bed. The contact has also been described as a fault¹⁸, but even so, Bed G-G' clearly seems to be younger than the marker-bed at Le Castella. This is because the entire 65 m of sandy Calabrian underlying Bed G-G' contains *Hyalinea baltica*²⁴ together with the various Pliocene/Pleistocene species of *Gephyrocapsa* noted above (Fig. 3; see also ref. 14) in an association that first appears at Le Castella only a short distance below the Pliocene/Pleistocene boundary (Fig. 2). The fact that *G. obliquus* has not been observed in the sandy Calabrian tends to confirm the correlation of this section to a level above the Le Castella marker-bed (see Fig. 5).

The presence of discoasters in the Catanzaro and Le Castella sections to levels well above the marker-beds has been cited^{14,16} as evidence that the Calabrian (and the Pliocene/Pleistocene boundary) is older than the Olduvai Event, but last occurrences of nannofossils are less reliable, due to reworking, than first occurrences as biochronological datums; in this particular case the argument that the sudden reduction in numbers of discoasters about 50 m below the Le Castella marker-bed represents the actual

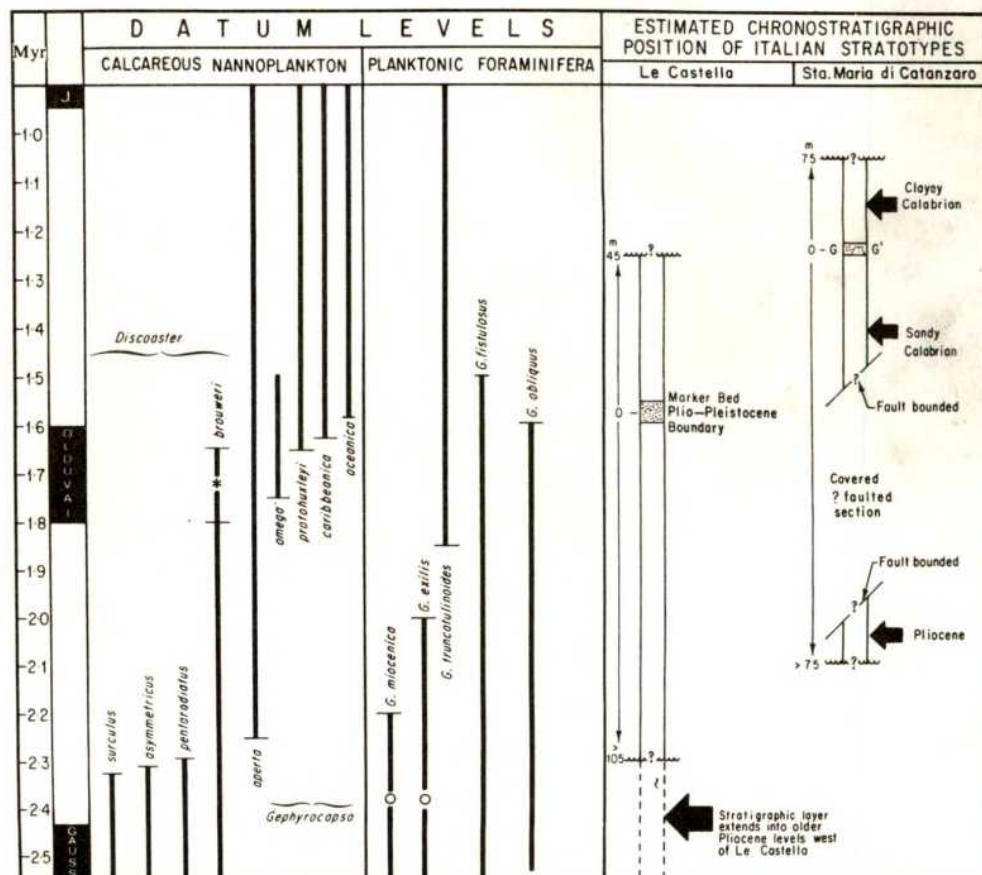

LAD agrees with the nanoplankton biostratigraphy in the deep-sea cores (Fig. 1). Thus, all of the discoasters collected in the Santa Maria di Catanzaro Calabrian (*s.l.*), both below and above Bed G-G' are probably reworked because they are stratigraphically above the FADs of *G. caribbeana* and *G. oceanica* and the LAD of *G. obliquus*.

We seem now to be faced with a paradox. According to the criteria already cited, Bed G-G' at Santa Maria di Catanzaro (which denotes the base of the stratotype of the Calabrian Stage) is younger than the marker-bed at Le Castella (which denotes the Pliocene/Pleistocene boundary). If this is so, then the section of sandy Calabrian below Bed G-G' is both Pliocene because it is pre-Calabrian, and Lower Pleistocene because it is younger than the Pliocene/Pleistocene boundary. By accepting the view that there is only one definition of the Pliocene/Pleistocene boundary, that of Le Castella, we resolve the paradox and simultaneously demonstrate the value of the 'golden spike' in picking apart such conundrums.

Calabrian, Emilian and Sicilian

The stage-subdivisions of the Italian Lower Pleistocene are based partly on geomorphological and continental evidence, and partly on marine invertebrate biostratigraphy, because of the environmental and stratigraphic effects of glacio-eustatic changes³. Radiometric dating^{3,32,33} of strata assigned to Pleistocene stages, therefore, is not clearly applicable to the marine sequence, nor is the marine sequence well-correlated. To cope with this, Ruggieri and his colleagues³¹ proposed the use of invertebrate datum events—the FADs of *Arctica islandica*, *Hyalinea baltica*, and *Globorotalia truncatulinoides*—to identify the beginning (base) of the successively younger Calabrian, Emilian, and Sicilian Stages, respectively. In this proposed arrangement, the section at Santa Maria di Catanzaro from Bed G-G' upward is specifically correlated to the Sicilian Stage of Palermo³¹ because the occurrence of *A. islandica* in Bed G-G' is (rightly) held to be accidental,

Fig. 5 Pliocene/Pleistocene calcareous plankton biochronology in deep-sea cores and estimated chronostratigraphic position of about 1.8 Myr (*) in one of the cores studied (V12-18). The upper limit of this species, as shown here, may thus be somewhat younger than the actual extinction datum, due to reworking at the depositional interface. ○, Atlantic only.

but the occurrence of *Globorotalia truncatulinoides* close to this level is held to represent the true FAD of this species and thus the base of the Sicilian.

Aside from violating the principle that stratotypes, not fossils, define a stage, the proposal³¹ is untenable on the basis of biostratigraphy cited here. First, *H. baltica* ranges down through the sandy Calabrian at Catanzaro²³, and down to 25 m below the Pliocene/Pleistocene marker-bed at Le Castella²⁴, which would indicate that these strata belong to the Emilian, not the Calabrian Stage, and that there is, apparently, no Calabrian in Calabria at all. Second, the occurrences of *Globorotalia truncatulinoides* in the Pliocene/Pleistocene of Calabria are rare and unreliable, and the evidence from areas where it is more abundant indicate that its FAD precedes that of *G. caribbeana* and *G. oceanica* (Fig. 5) and thus, one may presume, the FAD of *H. baltica* (see Fig. 2). In summary, to follow the proposal of Ruggieri and others³¹ in this region would first eliminate the Calabrian in its present form by invalidating its stratotype and burying it in the Sicilian Stage, and then would extend the base of the Sicilian (in theory) below that of the Emilian as well. These assumptions as to the relationships of the lower age limits of the proposed defining taxa are incorrect, or (in the case of the shallow-water mollusc *A. islandica*) not demonstrable, at least in the type Calabrian area.

Correlation of discoaster extinction level

We have observed that the extinction of discoasters at Le Castella, marked by a sudden drop in relative abundance of *D. brouweri* that signifies the transition from autochthonous to recycled status, is in close association with the sequential first appearance of various species of *Gephyrocapsa* (Fig. 2). The same relationship in the biostratigraphy of deep-sea cores that overlap the top of the Olduvai Event (Fig. 1) allows us to correlate the Pliocene/Pleistocene of Calabria to the deep-sea record (Fig. 5). Kaneps³⁴ has likewise observed that in equatorial-Pacific core RC12-66, the uppermost autochthonous occurrence of discoasters is within carbonate-minimum 17 near the top of the Olduvai Event, at about 1.65 Myr. But, at DSDP Site 132 in the Mediterranean this datum was found to be below Mediterranean carbonate-minimum M21, within the upper Gauss polarity-stage at about 2.6 Myr, and so it was suggested that the extinction datum of discoasters was correspondingly earlier in the Mediterranean basin than in the open ocean due to differential cooling of the Mediterranean. Our data suggest, on the other hand, that *D. brouweri*, the last of the discoasters, became extinct in the Mediterranean and in the tropical Pacific and Atlantic oceans almost simultaneously. The apparent diachroneity cited in DSDP Site 132³⁴ may be due to local effects, or to miscorrelation.

Palaeoclimatic history and the beginning of the Pleistocene

When the Pliocene/Pleistocene boundary was correlated to the beginning of the Olduvai Event according to the best data of a few years ago⁷⁻¹¹, oceanographers found that there were no identifiable major climate changes in the deep-sea record (the land record was simply too vague) that could be correlated to such a boundary. This seemed to justify a new approach to the boundary, implicit in the recommendation of the 1948 International Geological Congress³⁵ that the boundary be defined by the base of the Calabrian Stage in Italy—the beginning of the golden spike concept. Abandoning any reference to palaeoclimatology seemed healthy iconoclasm at the time, because of irritating and unreconcilable arguments that were beginning to arise out of radiometric dating on 'the earliest glacial event' ranging from 0.5 Myr to 3 Myr^{2,14} or more—evidently palaeoclimatic models had different attributes in different places.

The *Globorotalia truncatulinoides* datum has now proved to be a weak reed, and with the correlations described here we are on firmer, slightly different ground. It has long been supposed that the

change from Piacenzian clayey sediments to the markedly different lithology and colder-water fauna of the Calabrian was a reflection of Pleistocene climate replacing pre-glacial Pliocene^{1,6,27,28}, and the 1948 Commission referred to this in its recommendation³⁵. (For those unfamiliar with golden spikes, the reasons for establishing a physical reference point as a boundary definition become immaterial once the definition, or spike, is pounded in.) But, oceanographers, accustomed to the *truncatulinoides* connection, have habitually ignored or discounted the palaeoclimatic criterion as wishful thinking by workers bemused by over-dramatic concepts of the Ice Ages.

With the revised estimate of 1.6 Myr for the boundary, these conflicting concepts of the beginning of the Pleistocene seem to be reconciled. Synthesis of marine and nonmarine data for the Late Neogene had already shown that the first major glacial advance in North America, the Nebraskan, and correlative climate-induced effects elsewhere, should be dated close to 1.5 Myr³⁰, and that three others begin at approximately 0.9, 0.6, and 0.3 Myr respectively. More recently, quantitative factor-analysis and oxygen-isotope studies of microfossils in cores from the equatorial Pacific and tropical North Atlantic^{37,38} have been used to derive Pleistocene-palaeoclimatic curves. These show clearly-developed periodicities of 92,000 yr—as predicted long ago by Milankovitch according to computations of orbital precession and recently used, with varying success, in Late Pleistocene climatostratigraphy^{1,16,39}—superimposed on much broader and stronger climate cycles with a periodicity of about 500,000 yr. The earliest of four of these major cold-water, high-salinity, high-seasonality peaks seen in the North Atlantic core³⁷ centres at 1.5 Myr, just above the top of the Olduvai Event. This palaeo-oceanographic feature is clearly to be equated in age with the Nebraskan glaciation³⁶. From the data presented here, it can also be clearly equated with the Pliocene/Pleistocene boundary as defined by the marker-bed at Le Castella.

We thank the Lamont-Doherty Geological Observatory, F. Barbieri, Gulf Oil Corporation and M. Briskin for core and outcrop material studied here. D. Rio (Parma) has already published some conclusions about the relationship of the Calabrian marker-beds²³ that anticipate ours, with fewer data. D. Bayliss, C. Denham, D. Johnson, and T. Saito reviewed the manuscript. This research was supported by USNSF grant OCE 76-21274 (to B.U.H. and W.A.B.).

Cultured epithelial cells of cornea, conjunctiva and skin: absence of marked intrinsic divergence of their differentiated states

Tung-Tien Sun & Howard Green

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Keratinocytes of three different epithelia grown in cell culture express a large number of differentiation markers with either no differences or relatively small differences, depending on the species. Much of the distinctive phenotype of these epithelia in vivo must be due to external modulation and relatively little, at least in the case of the human, to permanent intrinsic divergence during development.

THE corneal and conjunctival epithelia and the epidermis are stratified squamous epithelia. Cells in the basal layer of all three seem similar, but differentiation in the superficial layers is obviously different. The corneal and conjunctival epithelia do not possess the granular cell layer and anucleate stratum corneum typical of epidermis. Since all three epithelia rise embryologically from closely related precursors, it is not surprising that they should share some common properties; but as these epithelia later become very different, they might be thought to have diverged markedly and irreversibly during embryogenesis.

With proper fibroblast support, human epidermal cells (keratinocytes) can be grown serially in cell culture^{1,2}, where they show many of the differentiation markers characteristic of this cell type *in vivo*. Single cells give rise to colonies, each forming a stratified squamous epithelium containing multiplying and differentiating cells. The cells synthesise keratins (T.-T.S. and H.G. unpublished) and grow in size, eventually forming cornified (cross-linked) envelopes^{3,4}. The final stages of epidermal differentiation are promoted by placing the cells in suspension—a condition which does not permit the cells to grow; instead they become permeable to Trypan blue, their keratin filaments become detergent insoluble, they form cross-linked envelopes, and with the aid of serum plasminogen, their nuclei are digested⁵.

We describe here the behaviour of corneal and conjunctival epithelial cells when grown in the same conditions. They can multiply and carry out the same programme of differentiation as the epidermal cells, including some aspects not observed *in vivo*. All three cell types are clearly keratinocytes and, at least in the case of the human, their behaviour in common culture conditions is so nearly the same that we are not able to distinguish them. In the case of the rabbit, there are some persistent, though small, differences between the keratinocytes of different origin.

Fibroblast dependence and effect of EGF

In earlier studies of cultured corneal epithelial cells, fibroblast support was not provided⁶⁻⁸, but epidermal keratinocytes have since been found to require the support of fibroblasts in order to form colonies¹. This support was usually provided in the form of lethally-irradiated 3T3 cells at a density of about $20,000\text{ cm}^{-2}$ inoculated together with or before the keratinocytes. In these conditions, the keratinocytes form expanding colonies, displacing the 3T3 cells from the vessel surface. The epidermal cells are serially cultivable and grow through many cell generations. In the human, epidermal cells do not transform into established lines and retain the diploid chromosome number¹.

This culture system was applied to epithelial cells of cornea and

conjunctiva. Human corneas were obtained from local eye banks and after the endothelial layer and Descemet's membrane were removed with jeweller's forceps, the remaining tissue (epithelium plus a small part of the stroma) was minced to approximately $1-2\text{ mm}^3$ and digested with 0.25% trypsin and 0.002% EDTA at 37°C for 30–45 min. The disaggregated single cells were then plated with irradiated 3T3 cells. Multiplication of human fibroblasts was inhibited by the 3T3 cells, but if necessary, human fibroblasts were selectively removed with 0.02% EDTA after the epithelial colonies grew to appreciable size^{1,3}.

Figure 1 shows subcultures containing corneal epithelial and epidermal colonies 11 d after inoculation of 5×10^4 cells together with irradiated 3T3 cells. The colonies stained red with Rhodanile Blue and were of similar size and appearance. In the absence of 3T3 cells, neither epithelial cell type formed colonies; as there were no fibroblast colonies either, the cultures did not contain appreciable numbers of living human fibroblasts.

In the presence of epidermal growth factor⁹ (EGF), the cells of large colonies of epidermal keratinocytes sustain their growth rate much better than in its absence². Corneal epithelial cells were similarly responsive, judging from the size of the colonies (Fig. 1). Such an effect of EGF is to be expected from its action on intact corneal epithelium¹⁰. Conjunctival epithelial cells were similar to corneal epithelial cells in their colony-forming properties and EGF responsiveness.

When examined under the phase microscope, the basal cells of colonies of human corneal epithelial cells (Fig. 2a) seemed similar to those of epidermal cells (Fig. 2b) in their shape, their mosaic-like arrangement and their ability to displace the 3T3 cells from the vessel surface. The stratified structure of the colonies, and the silver-staining properties of the superficial cells³ were also very similar.

Four strains of corneal epithelial cells, originating from donors aged between 25 and 60, and growing in the presence of EGF, were subcultured twice and grew through a total of about 30 cell generations. Although epidermal cells of newborn donors can grow through many more generations², the culture lifespan of corneal epithelial cells in the present experiments seems similar to that of epidermal cells of adult donors¹.

Synthesis of keratins and other cellular proteins

The keratins of bovine epidermal stratum corneum have been characterised electrophoretically^{11,12}. Those of cultured human epidermal cells and human stratum corneum have recently been found to be similar in solubility, electrophoretic behaviour, immunological reactivity and ability to assemble into filaments *in vitro* (T.T.S. and H.G., unpublished).

The proteins of cultured epidermal, corneal and conjunctival epithelial cells were compared by electrophoresis in polyacrylamide gels containing sodium dodecyl sulphate (SDS). Figure 3a (track 1) shows the total protein of human corneal epithelial cells extracted with 2% SDS and 1% β -mercaptoethanol. Identical patterns were obtained from epidermal and conjunctival cells. In addition to the large number of protein bands unrelated to keratins, there were present several intense bands of keratins with a molecular weight range from slightly greater than that of actin (42,000) to slightly greater than that of tubulin (55,000). The non-

Fig. 1 Colony formation, fibroblast dependence and the effect of EGF. Human corneal epithelial cells (5×10^4 , strain B, donor aged 25 yr, secondary culture) and epidermal cells (5×10^4 , strain M, newborn donor culture) were plated in 60-mm dishes with or without 4×10^5 lethally-irradiated 3T3 cells. To some dishes, epidermal growth factor (EGF) was added to a final concentration of 15 ng ml^{-1} , starting on the third day after plating². After a total of 11 d, the cultures were fixed with 10% formalin and stained with Rhodanile Blue¹⁹.

keratin proteins can be removed selectively by extraction in dilute buffer, leaving substantially only the keratins to be extracted with SDS and reducing agent (Fig. 3a, tracks 2–5). Tracks 2, 3 and 4 show no consistent differences in the position or relative intensity of the keratin bands of corneal and conjunctival epithelial cells and of epidermal cells. No keratins were detected in fibroblast extracts (track 5).

In order to compare the keratins of the different cell types further, antiserum specific for epidermal keratins of human stratum corneum was prepared and tested in double diffusion experiments against an extract of the total protein of each cell type. It was found that the proteins of cultured epithelial cells of epidermis, cornea and conjunctiva reacted strongly with the antiserum and showed a precipitin band in common with one of the bands produced by the keratins of stratum corneum (Fig. 4). A second precipitin band produced by the keratins of stratum corneum was not present in any of the cultured cell types and may have been due to a 63,000-molecular weight protein known to be present in stratum corneum, but not in corneal epithelium or any cultured keratinocytes (unpublished). No visible precipitin band was produced by the proteins extracted from human fibroblasts.

Increase in cell size and formation of cross-linked envelope

During differentiation in culture, human epidermal cells increase their cell size and protein content³ as they do *in vivo*¹³. Figure 5a shows that, like epidermal cells, trypsin-disaggregated corneal epithelial cells adopted an approximately spherical shape and could be seen to vary greatly in size. The smallest cells, which are probably the basal cells³, had a diameter of about $12 \mu\text{m}$. The

Single colonies of corneal epithelial and epidermal cells. Primary colony of corneal epithelial cells of strain B (a) and secondary colony of epidermal cells of strain M (b) 11 d after inoculation. The cultures were fixed with buffered 10% formalin and photographed directly without staining. One margin of each colony appears in the right hand side of the pictures. Phase-contrast microscopy.

largest cells, probably the superficial cells of the epithelium³, exceeded 35 μm in diameter. Some of the large cells possessed cross-linked envelopes similar to those made by terminally differentiated epidermal keratinocytes. The presence of these envelopes was demonstrated by heating a trypsinised cell suspension in the presence of 5% SDS and 1% β -mercaptoethanol, a procedure which dissolves entirely cells without such envelopes but only the intracellular contents of cells with envelopes³ (Fig. 5b). The insolubility of the envelopes is due to proteins cross-linked by ϵ -(γ -glutamyl)-lysine bonds⁴. As in the case of epidermal cells, usually 5–10% of the cells in surface cultures of corneal epithelial cells possessed cross-linked envelopes.

Cross-linked envelopes were also found in human corneal epithelium *in vivo*. Samples were scraped from the surface of excised corneas with a knife, and treated directly with detergent and reducing agent. Microscopic examination showed that envelopes were abundant. These envelopes preserved the flattened shape of the cells *in vivo*, as they do even in cultures of epidermal

The proteins of cultured epithelial cells of cornea, conjunctiva and epidermis. *a*, Human, 3T3 cells were removed from nearly confluent epithelial cultures with isotonic buffer containing EDTA (refs 1, 3). The epithelial cells were collected in a small volume of the same buffer with the aid of a rubber policeman. Half of the cells were extracted directly with a solution of 2% SDS and 1% β -mercaptoethanol at 100 °C for 5 min. The extract was analysed by 12.5% disc polyacrylamide gel electrophoresis in the presence of SDS. The other half of the cells were first extracted with several changes of 100 vol 20 mM Tris-HCl (pH 7.4) and the insoluble proteins were then dissolved in detergent and β -mercaptoethanol as before and subjected to electrophoresis; protein (50–100 μg) was applied to each slot. The direction of electrophoresis was from top to bottom. Numbers on the right hand side of the gel denote molecular weights of standard proteins including human serum albumin (68,000), tubulin (57,000 and 55,000), the heavy chain of human gammaglobulin (50,000), and actin (42,000). The bracket at the left hand side of the gel indicates the mobility range of the keratin proteins. Samples in different tracks are: 1, total proteins of cultured human corneal epithelial cells; 2, insoluble proteins of the same cultured corneal epithelial cells; 3, insoluble proteins of cultured conjunctival epithelial cells; 4, insoluble proteins of cultured epidermal keratinocytes; 5, insoluble proteins of cultured human foreskin fibroblasts. Any apparent difference in band intensity between the extracts of the three epithelial cell types was not reproducible. *b*, Rabbit, 12-d-old primary cultures of corneal epithelial cells and epidermal cells derived from the same 1-yr-old animal were collected. Total cellular protein was extracted and analysed as for the human. Arrows show two non-keratin proteins present only in the corneal epithelial cells. The keratin bands, which lie between actin and molecular weight 57,000, differ slightly in mobility from those of the human and may be less abundant. RCE, Rabbit corneal epithelial cells; RSE, rabbit epidermal cells; Std, molecular weight standards.

Fig. 4 Immunological cross-reactivity between keratins of human stratum corneum and proteins of cultured human epithelial cells. Stratum corneum was minced and pre-extracted with 8 M urea to remove non-keratin proteins. The keratins were then dissolved in 8 M urea containing 10 mM dithiothreitol. Rabbits were immunised at multiple sites with a total of 20 mg protein over a period of 2 months. Antiserum thus obtained was placed in the centre well of an Ouchterlony plate and tested against 80–120 μg of total cell protein of different cell types extracted with a solution containing 1% SDS, 10 mM dithiothreitol and 10 mM Tris-HCl (pH 7.4). 1, Keratins of stratum corneum (30 μg); 2, extract of cultured epidermal keratinocytes; 3, extract of cultured corneal epithelial cells; 4, extract of cultured conjunctival epithelial cells; 5, extract of cultured human dermal fibroblasts. The double diffusion test was performed in an agar plate containing 0.1% SDS, 0.5% Triton X-100, 0.01% Thimerosal, in addition to phosphate buffer and 1% Agarose, basically according to Yen *et al.*²⁰.

keratinocytes when the cells are treated with the reducing agent and detergent without previous trypsinisation³.

Terminal differentiation of suspended cells

When human epidermal cells are suspended as single cells in medium stabilised with methylcellulose (methocel), they develop disulphide-stabilised keratin filaments and become insoluble in SDS solutions. These conditions also greatly favour the formation of cross-linked envelopes. Eventually, the cell nuclei are destroyed⁵.

By all three criteria, human corneal epithelial cells were found to behave similarly. Within a few days in suspension, all the cells became insoluble in detergent, and about 50% developed cross-linked envelopes (Fig. 6). About 80% of the cell nuclei were destroyed within 9 d.

Properties of rabbit keratinocytes in culture

In order to compare the same cell types from another species, experiments were carried out on epidermal and corneal epithelial cells of the rabbit (newborn to 1 yr old). Both formed stratified squamous epithelial colonies in surface culture and developed detergent-insoluble keratin filaments and cross-linked envelopes in suspension. Both cultured cell types were shown to possess desmosomes and tonofilaments on electron microscopic examination, and both contained keratins demonstrable by electrophoresis (Fig. 3b). It is clear that, as in the human, both cell types are keratinocytes; the two cell types of the rabbit could, however, be distinguished in culture. For example, although the corneal epithelial cells formed cross-linked envelopes in methocel suspension, they did so with lower frequency than epidermal cells and did not form envelopes at all in surface culture. This is perhaps related to the fact that, unlike that of the human, the corneal epithelium of the rabbit *in vivo* does not possess cells with cross-linked envelopes. Rabbit corneal epithelial cells grew poorly on subculture in comparison with the epidermal cells. Finally, the

cultured rabbit corneal epithelial cells contained two water-soluble non-keratin proteins not present in epidermal keratinocytes (Fig. 3b).

External modulation or intrinsic divergence of differentiated state

By the criteria already described, the cultured cells of all three epithelia are keratinocytes (to be distinguished from fibroblasts of corneal stroma, sometimes referred to as keratocytes). In the human cell cultures we have been unable to distinguish the three cell types by any criterion. The same differentiation markers can be expressed in culture by epidermal and corneal epithelial cells of the rabbit, although the culture phenotypes of the two cell types are not identical. These results suggest that an important part of the differences between these epithelia *in vivo* results from differences in the local environment in which the cell type is found.

One obvious local difference is related to the adhesiveness of the superficial cells of the epithelium. A dry-surfaced epithelium (skin) invariably possesses an anucleate stratum corneum, whereas wet-surfaced epithelia frequently do not. Whether an anucleate cell layer is present or not may simply be a matter of the adhesiveness of the superficial cells, which in turn could be affected by the degree of hydration. If adhesiveness is low, detachment may occur before differentiation is complete. This occurs in surface cultures of epidermal keratinocytes; nuclear destruction is completed, for the most part, after detachment of the squames⁵, rather than before, as in intact skin. Similarly, we have shown here that nuclear destruction takes place in corneal keratinocytes suspended in methocel much as it does in epidermal keratinocytes, although corneal epithelium does not normally possess a stratum corneum.

A second and perhaps more important difference is related to the nature of the cells located beneath the epithelium. Instructive effects of the underlying connective tissue are known to specify keratinocyte behaviour in adults¹⁴ as well as in embryonic life¹⁵. In our cultures of the various epithelia, the fibroblast population consists mainly of (irradiated) 3T3 cells. For the reasons mentioned, fibroblasts of the type associated with the epithelium *in vivo* were virtually absent from the cultures studied. The very similar phenotype exhibited by the cultured keratinocytes might be explained by either absence of specific fibroblast instruction or the presence of common instruction provided by the 3T3 cells. The possibility exists that any one of these keratinocyte types, especially in the human, placed in the *in vivo* site of one of the other, even after birth, would conform in phenotype to the other keratinocyte type and generate the site-specific epithelium^{14,16}.

Fig. 5 Cell enlargement and formation of cross-linked envelopes by cultured human corneal epithelial cells. *a*, Heterogeneity of cell size in the growing colonies. 3T3 cells and any contaminating living fibroblasts were removed selectively from a nearly confluent 17-d primary culture with EDTA. The remaining corneal epithelial cells were trypsinised and an aliquot of the single-cell suspension examined in a haemocytometer chamber under the phase microscope. Note the presence of cells of variable diameter from 12 μm to > 35 μm . *b*, Cross-linked envelopes formed in surface culture. To a trypsinised single-cell suspension of cultured human corneal epithelial cells, SDS and β -mercaptoethanol were added to final concentrations of 5% and 1% respectively and the solution was heated to 100 $^{\circ}\text{C}$ for 3 min. The photograph taken under phase microscopy shows several of the large envelopes remaining. All small cells are dissolved.

Fig. 6 Terminal differentiation of human corneal epithelial cells in methocel-stabilised suspension. Thirteen-day tertiary cultures of human corneal epithelial cells grown in the presence of EGF were trypsinised and resuspended at 2×10^5 cells ml^{-1} in medium containing 20% foetal calf serum and 1.2% methylcellulose. Aliquots were removed at intervals, diluted in isotonic buffer and the cells centrifuged. Cells insoluble in detergent (○) alone possess disulphide-stabilised keratin filaments. Cross-linked envelopes (□) were scored by insolubility in ionic detergent plus reducing agent. Cells were also deposited on filters, fixed and stained with haematoxylin and eosin, and the proportion of cells possessing nuclei was determined⁵. ●, Anucleate cells.

3T3 cells are known to be fibroblasts¹⁷, but it is not known from what organ they originated, as the line was evolved from mixed mouse embryo cell cultures¹⁸. This may not be important insofar as ability to support proliferation is concerned, since human diploid fibroblasts of non-dermal as well as of dermal origin support the growth of epidermal keratinocytes^{1,19}. The experiments described here also show that the ability of 3T3 cells to support keratinocyte multiplication is not specific for the type of keratinocyte. Although the fibroblast products necessary for the support of keratinocyte growth have not yet been identified, they may be different from those involved in instructive effects.

Whatever the special conditions that may modulate their differentiated state *in vivo*, the three cell types can, in the human, show a common phenotype in culture in which all the properties examined, including the differentiated ones, are expressed equally. In the case of the rabbit, although all the differentiated properties can also be expressed in culture by corneal and epidermal cells, the differences between the two cell types grown in identical culture conditions show that conversion to a common phenotype is not complete. Thus in this species, the intrinsic differences may make a significant contribution to the phenotypic differences between the two epithelia *in vivo*.

These investigations were aided by grants from the National Cancer Institute. Human corneas were provided from local eye banks by Drs Beatrice Y. J. T. Yue, and Jules L. Baum and Miss Rasma Niedra.

letters to nature

Rapid fluctuations of radio flux and polarisation in quasar 3C273

QUASAR 3C273, one of the brightest and most studied quasars, is variable over a wide wavelength range. The changes of its luminosity may occur on a timescale of a few years or of several days in both the radio¹ and optical^{2,3} range. There are variations of linear and circular polarisation in the radio domain⁴ and sometimes the optical emission is circularly polarised⁵. The data from our simultaneous radio and optical observations show rapid variations of radio flux and circular polarisation at $\lambda = 1.35$ cm, and of optical linear polarisation of 3C273 within one day or several hours. These variations are possibly more rapid than those previously reported.

Total flux I and intensity V of circular polarised emission at 1.35 cm of the quasar 3C273 were measured during March–April 1976 using the 22-m radio telescope of the Crimean Astrophysical Observatory. The angular resolution of the radio telescope was $2.5' \times 2.6'$ and the sensitivity was about 0.7 Jy with a time constant of 1 s using a switched receiver with a maser as a high-frequency pre-amplifier. Beam switching in the azimuth plane was used to reduce the influence of fluctuations of atmospheric radio emission. The quarter-plate analyser was placed behind the central circular feed. The main and reference beams had orthogonal polarisation and measurements of flux I were made by an 'on-off' method similar to that described in ref. 6. A minicomputer operating on-line processed the output signals of the receiver and checked its amplification⁷. Flux density was measured relative to the standard sources Saturn (brightness temperature 128 ± 5 K) and the thermal source DR21 (flux density 19.5 ± 0.6 Jy). The water line at 1.35 cm lies in the received band, so the atmospheric attenuation may be variable. Therefore, to eliminate the influence of the atmospheric extinction variations the standard sources and the control source 3C274 were measured just before or after 3C273 and at about the same zenith distances. The corrections for extinction in this case did not exceed a few per cent. The r.m.s. error of the total flux determined with the aid of 3C274 does not exceed 2.5%. Zero level for parameter V was found by observation of DR21 which is expected to have zero circular polarisation; it showed no fluctuations in excess of the r.m.s. errors (its mean value found here is $-0.35 \pm 0.07\%$ where minus corresponds to left-handed polarisation).

Concurrently with radio observations of 3C273 optical observations were carried out with a polarimeter⁸ at the Cassegrain focus of the 2.6-m Crimean reflecting telescope. The optical intensity and the linear polarisation were recorded in B and V spectral bands with $\lambda_{\text{eff}} = 430$ and 540 nm respectively. The optical flux was measured with

respect to the comparison star 50" to the West of 3C273 and polarisation was calibrated with the aid of standard stars⁹.

The results of radio and optical measurements are shown in Fig. 1. They sometimes show rapid intensity fluctuations

Fig. 1 *a*, Variations of the radio flux of 3C273 at 1.35 cm; *b*, the degree of circular polarisation 3C273 at 1.35 cm; *c*, the radio flux of control source 3C274; *d*, the optical brightness 3C273 at the B band in magnitudes; *e*, the degree of linear polarisation of optical radiation in the B (●) and V (○) bands. Vertical bars show the value of r.m.s. error.

of radio emission of 3C273 in a period of one day (22 and 29 March, 5 and 7 April) whereas the optical brightness remains nearly constant. The total (peak-to-peak) amplitude of relative variations of the radio flux from 3C273 is 33%, twice as large as that of the control source 3C274. The ratio of corresponding dispersions is 11.3 and is statistically significant at the $<0.5\%$ level. On the two days 22 and 29 March, variations of the radio flux of 3C273 reaching 20% were observed over about 4 h, although the intensities of 3C274 measured at the beginning and at the end of these runs did not differ significantly. The rapid decrease of radio flux on 29 March was accompanied by an increase in the degree of circular radio polarisation p_c from the average value of $0.24 \pm 0.07\%$ to $2.1 \pm 0.2\%$ and by the appearance of the optical linear polarisation beyond the 3σ range. Another such fluctuation of optical linear polarisation took place near 7 April when the radio flux was also at a minimum. The planes of polarisation on these two occasions were quite different (see Fig. 2).

Fig. 2 Diagram of normalised Stokes parameters Q/I and U/I for optical linear polarisation of 3C273 at the B band. 1, 24 March; 2, 29 March; 3, 30 March; 4, 3 April; 5, 4 April; 6, 7 April 1976. Bars show the r.m.s. errors of each parameter.

A similar phenomenon, but with a slower decrease of the flux of 3C273 by 20%, was observed earlier at a wavelength of 3.5 cm on 23–27 May, 1969 (ref. 9). There is also a report about the decrease of the flux density at 7.2 cm of another source OJ287 of the same amount (20%) over about 2 h (ref. 10). It is remarkable that in OJ287 there is a similar correspondence between daily variations of its flux at 1.35 cm and that of optical linear polarisation as in the case of 3C273 mentioned here: optical emission is more polarised near the minimum radio flux^{11,12}.

The observed fluctuation of linear (in optical range) and circular (in radio range) polarisation could eventually be connected with possible rapid changes of transversal and longitudinal components of magnetic field in the quasar 3C273 during the periods of strong diminution of radio flux. This also agrees with the earlier observations of temporary appearance of circular polarisation in the optical range reported in ref. 5 and of the variations of the linear and circular polarisation of this quasar at radio wavelengths⁴.

We thank Professor A. B. Severny for drawing our attention to the possibility of a fast variability in 3C273 and for his interest in our investigation.

New high energy γ -ray sources observed by COS B

LOCALISED γ -ray sources contribute to the overall galactic emission; some of these sources have been identified with known astronomical objects^{1,2}, while several unidentified γ -ray sources have also been reported^{3,4}. We describe here a search for γ -ray sources using data from the ESA γ -ray satellite COS B which revealed 10 new unidentified sources. These sources seem to be galactic with typical γ -ray luminosities above 100 MeV in excess of 10^{35} erg s⁻¹.

The COS B satellite was launched in August 1975, and most of its (typically 1-month) observations have been devoted to a sensitive survey of the galactic plane. The characteristics of the instrument and the important features of the mission are described elsewhere^{5,6}. The data from four of the observation periods, for which manual analysis procedures⁶ are complete, have been analysed for sources of γ rays of energy > 100 MeV, using a method which yields an angular resolution of about 2.5° (FWHM). In each case the search has been limited to a region 40° wide in galactic longitude and 30° wide in latitude centred on the pointing direction. The method of analysis has been described in detail elsewhere⁷.

From the γ -ray intensity distributions the statistically most significant enhancements⁷ have been taken together with PSR0833–45, to compile the catalogue of γ -ray sources shown in Table 2. The nomenclature CG $n+m$ is introduced for a γ -ray source detected by COS B at longitude n° and latitude m° (truncated values). Table 2 lists the galactic coordinates, and the intensities above 100 MeV relative to the Crab (CG185–5). The indicated uncertainties in the relative intensities include systematic errors, reflecting possible changes in the instrument sensitivity, for which corrections are being derived. The intensity of CG185–5 above 100 MeV of $(3.5 \pm 1.0) \times 10^{-6}$ photon cm⁻² s⁻¹, is found to agree with other measurements⁸.

The latitude distribution of the detected sources, shown in Fig. 1, immediately indicates their galactic nature. The absence of sources between 7° and 15° is particularly significant because the visibility of sources increases with galactic latitude due to the

Table 1 Observations used in the search for localised sources

Pointing direction μ°	b°	From	To
185	-6	17 August	17 September 1975
74	0	28 November	24 December 1975
322	0	23 February	24 March 1976
126	1	24 June	25 July 1976

decrease in the background flux contributed by the galactic disk. The distribution suggests typical distances in excess of 1 kpc which, coupled with typical flux values of 10^{-9} erg cm $^{-2}$ s $^{-1}$, leads to individual luminosities in excess of 10^{35} erg s $^{-1}$.

The nature of this new class of astronomical objects is intriguing. The positional errors virtually exclude unique identification with a known object, and the finite angular resolution makes it impossible to distinguish between a compact object and an emission region of angular dimension up to 2°. Although our results may not be representative for the entire galaxy, the sources do contribute significantly to the overall γ -ray luminosity of the galaxy, in the anti-centre region even accounting for most of the emission⁹.

Table 2 γ -Ray sources detected by COS B

Source	$l^{\text{II}}(^{\circ})$	$b^{\text{II}}(^{\circ})$	Relative intensity	Remarks

The suggestion by Black and Fazio¹⁰, that interstellar clouds could be γ -ray sources when bombarded by cosmic-ray protons, has been investigated. If the density of cosmic rays is the same beyond 1 kpc as is measured locally, masses in excess of $10^6 M_{\odot}$ would be required to account for the observed source intensities. No such massive clouds have been observed near the locations of the reported γ -ray sources.

A search for possible X-ray counterparts of the γ -ray sources has also been made. The weak sources 4U0241+61 and 4U1416-62 (ref. 11) are within the error boxes of CG135+1 and CG312-1 respectively. The soft source Cyg X-7, associated with the supernova remnant DR4 (ref. 12) falls within the error box of CG78+1. In addition, hard X-ray emission from the region of CG135+1 has been reported¹³. Such positional coincidences, however, provide only a weak argument for correlation in view of the high density of X-ray sources and the size of the γ -ray error boxes. In any case the absence of strong X-ray counterparts implies that the new γ -ray sources have substantially higher luminosities above 100 MeV than in the 2-6-keV band. It is noted that CG78+1 is not positionally coincidental with Cyg X-3, for which strong periodic γ -ray emission at an earlier epoch has been reported¹. Moreover, a search for the 4.8-h periodicity in the γ -ray emission from this region has yielded a negative result¹⁴.

Of the 149 known radio pulsars only PSR0531+21 and PSR0833-45 are confirmed γ -ray emitters. Of the remainder only one (PSR0611+22) falls within the error box of one of the COS B sources (CG189+1), for which a search for pulsating γ -ray emission has been inconclusive¹⁵.

Future steps towards a better understanding of the results presented here should include: (1) sensitive searches for radio pulsars and weak X-ray sources near the positions of the unidentified sources and (2) searches for timing signatures from candidate counterparts; in this context it is noted that CG195+4 shows periodic variations¹⁻¹⁰. This search is far from complete, as only one-third of the galactic plane has been effectively studied. Further analysis of available COS B data will provide a galactic distribution of γ -ray sources which will permit a comparison with other galactic populations.

Fig. 1 Latitude distribution of γ -ray sources. The shaded area indicates the identified γ -ray sources PSR0833-45 and PSR0531+21.

The COS B mission is planned to continue until the end of 1978. Although much of the observation time is to be devoted to prolonged observations of the galactic plane from $l^{\text{II}} = 340^{\circ}$ to $l^{\text{II}} = 90^{\circ}$, special observations to check on the consistency of suggested counterparts for already detected sources may be considered.

Positions of galactic X-ray sources Cir X-1, TrA X-1 and 3U1626-67

THE positions of three celestial X-ray sources were measured with the rotating modulation collimators (RMC) on SAS-3 during a survey of the galactic plane¹ and are precise to $\leq 25''$ (ref. 2). One of these sources, Cir X-1 (ref. 3), is a highly variable X-ray source often compared with the black-hole candidate, Cyg X-1. Another, TrA X-1 = A1524-61, is a 1974 X-ray nova⁴, and the third, 3U1626-67 (ref. 5), is a 7.68-s X-ray pulsar⁶. The results reported here support recently proposed optical and radio identifications⁷⁻⁹ of these three sources. In two cases (TrA X-1 and 3U1626-67), they have been instrumental in bringing about the proposed identifications. Cir X-1 exhibits a binary periodicity¹⁰ of 16.6 d, extreme aperiodic variability on timescales of > 0.1 s (refs 11, 12) and 1-3 s (ref. 13), and flaring^{14,15} with time constants of a few ms. This variability and the absence of a shorter (spin) period^{13,15} have led to suggestions^{11,13-15} that this object may be similar to Cyg X-1. The absence of a compelling optical or radio counterpart, however, has prevented the further exploration of this hypothesis.

Fig. 1 X-ray positions and error regions (90% confidence) for *a*, Cir X-1 and *b*, TrA X-1. The Ariel V, A, (refs 19, 8); Uhuru, U, (ref. 11) and SAS-3, 1S, (ref. 21) results precede the present work, 2S. The locations of the optical and radio counterparts^{7,8} are indicated. (Finding charts are presented in refs 7 and 8).

A faint ($R \sim 16-17$, $B-R \sim 6$) optical star with strong H α emission¹⁶ and a flaring radio source^{17,18} have been proposed as counterparts to Cir X-1 on the basis of Uhuru^{5,11} and Ariel V¹⁹ X-ray positions. The radio source has been shown⁷ to lie within $2''$ of the H α star and the radio flares have been observed to occur 0.5-3.0 d after several of the periodic (16.6-d) X-ray eclipses. This establishes its identification and its present

2S1627-673

Fig. 2 Finding charts for the source 3U1626-67 = 2S1627-673. The optical candidate is star 4 (ref. 9).

position (Fig. 1, Table 1) removes any remaining doubt about the association of the X-ray source with the radio-optical star.

TrA X-1 was a classic X-ray nova first observed on 12 November 1974 with the Ariel V satellite⁴. It became as bright as the Crab Nebula on ~ 3 December 1974 and decayed with a time constant of ~ 2 months²⁰. SAS-3 was launched in May 1975, and the source was detected with the RMC system in June 1975. Preliminary analysis of the SAS-3 data yielded a position²¹ accurate to $1.5'$. This together with a revised Ariel V position has made possible the recent discovery⁸ of an optical nova that was observed at $B = 17.5$ on a plate taken 15 December 1974 with the Anglo-Australian Telescope. The star subsequently faded with a time constant of ~ 117 d. Earlier limits of $B > 19.5$ and $R > 19$ were obtained 20 and 5 months respectively before the X-ray maximum⁸. The present refined SAS-3 position, accurate to $20''$, lies $14''$ from the position of the optical nova (Fig. 1).

The source 3U1626-67 recently was found⁶ to be a 7.68-s pulsar with no evidence for a binary Doppler shift ($P_{orb} \lesssim 0.5$ d or $P_{orb} \gtrsim 35$ d). It has a hard X-ray spectrum and is variable⁶ by a factor 3 on timescales of 100-300 s. Shortly after the discovery of the periodicity, the position of the X-ray source was measured with SAS-3. The celestial area defined by the measurement is smaller by a factor of 50 than that previously obtained⁵ with Uhuru. An optical study of this SAS-3 error region led to the suggested identification⁹ of a $V = 18.5$ star (4 in Fig. 2) as the counterpart because of its large ultraviolet excess ($U-B = -1.2$ and $B-V = +0.2$).

The existence of correlated temporal behaviour has firmly established the identifications of two of the sources, Cir X-1 (ref. 7) and TrA X-1 (ref. 8). The proposed identification⁹ of 3U1626-67 is probably correct because of the small X-ray error

Atmospheric waves in the ionosphere due to total solar eclipse

CHIMONAS¹ predicted that the 'cooling spot' of the lunar shadow of an eclipse, which travels at supersonic speeds through the atmosphere, is a continuous source of atmospheric gravity waves. These gravity waves show up by their interaction with the ionosphere and can be detected using standard radio techniques. Total electron content measurements² in the USA at a distance of several thousand km from the path of totality, detected oscillations which were attributed to a solar eclipse in agreement with the theory of Chimonas³. Measurements made during the 1973 central African eclipse⁴ failed to detect any oscillations, although these results may have been obscured by the occurrence of a magnetic storm at the same time. We present here the results of measurements made on the angle of arrival of a high frequency radio wave inside the path of totality of an eclipse, which took place on 23 October 1976.

The angle of arrival of a continuous wave (CW) obliquely propagated signal on 2.5 MHz was used over a short path of 71.4 km, from Lyndhurst (38°33'S, 145°16'E) to Beveridge (37°28'S, 144°56'E). On 23 October 1976, a total eclipse of the Sun occurred. The radio path was in the path of totality. Two different ionosondes were operated at Beveridge on the eclipse day. A phase path ionosonde, gating at about 100 km, gave group and phase path variations on 2.1, 2.4 and 2.9 MHz and results obtained from this ionosonde indicated that there were always E-region reflections during the eclipse which did not vary by more than ± 5 km. A digitised ionosonde, which records the strongest returned signal, gave ionograms every 45 s. These

ionograms indicated that E_s at a group height of 101 km appeared with a critical frequency $f_o E_s$ of 2.2 MHz at 1619, and at 1621 LT this E_s had an $f_o E_s$ of 2.4 MHz (this is just above the equivalent vertical frequency of 2.35 MHz, assuming a group height of reflection of 100 km). At 1624 LT $f_o E_s$ was 2.2 MHz and at 1625 LT it was 2.7 MHz and gradually increased to over 3.1 MHz at 1630 and remained so until after 1730 LT.

At the start of totality (~ 1642 LT) distinct oscillations with a period of 6-7 min were observed in the angle of arrival. Assuming that the oscillations observed were due to changes in the tilt angle of the sporadic E layer and to a minor extent height variations, it can be shown that the tilt angles along, γ_L , and across, γ_C , the propagation path, are given by

$$\gamma_L = \frac{1}{2} \left\{ \phi' - \frac{\pi}{2} + \tan^{-1} \left(\frac{1}{2 \tan \phi_0 - \tan \phi'} \right) \right\}$$

$$\gamma_C = \tan^{-1} \{ \sin(\theta - \theta_0) \tan \phi \}$$

where $\phi' = \tan^{-1} \{ \tan \phi \cos(\theta - \theta_0) \}$, θ and ϕ are the measured azimuth (bearing) and zenith angles and θ_0 and ϕ_0 are the angles expected for the case of a simple horizontally stratified ionosphere (including a horizontal sporadic E layer). Using the theorem of Breit and Tuve⁵, ϕ_0 was obtained from the group height of the sporadic E layer (assumed to be constant during the relevant period) and γ_L and γ_C were determined. They are shown as a function of time in Fig. 1a and b, several points are

Fig. 1 Variation of the tilt angle of the sporadic E layer with time: a, along the propagation path; b, across the propagation path. A, E_s appeared; B, onset of totality.

evident: (1) between 1625 LT and totality, the E_s layer had an apparent average systematic tilt in γ_L (along the path) of about 6° with a small oscillation superimposed on it. (2) Just after totality this apparent tilt changes considerably and returned to its previous value slowly over about 40 min. (3) During this return, several cycles of a damped oscillation initially of large amplitude occurred of period 6-7 min. (4) No such variations were observed in γ_C (that is across the path).

Between 1619 and 1625 LT, an apparent single oscillation also occurred. As mentioned above, during this period the E_s layer was forming. The digitised ionosonde records indicated that we were only getting strong E_s reflections near 1621–22 LT. The phase ionosonde records indicated that we were still getting E-region reflections near 1619–20 and 1623–24 LT. Since before 1620 reflections from the normal E-region indicated a tilt of $1-2^\circ$, the excursion at 1621–22 is probably due to a reflection from the E_s during its formation.

Chimonas¹ applied his theory to the free bow-wave in the atmosphere outside the penumbra, where the wavefronts of the gravity waves in a previously still atmosphere were expected to be emitted at an angle η to the eclipse where η is given by

$$\tan \eta = V_G/V_E$$

and V_G is the velocity of the atmospheric wave at the altitude concerned (101 km). Taking $V_G = 300 \text{ ms}^{-1}$ and V_E as the velocity of the Moon shadow the wave would be expected to be propagated in a direction $\sim 166^\circ$ south of north (geographic) which is almost along the path between Lyndhurst and Beveridge (it being $\sim 157^\circ$ south of north (geographic)). Hence, outside the shadow, the oscillations due to the eclipse might be expected to be only in γ_L for our geometry. (It might be expected that the changes in the intensity of the solar radiation near totality would cause changes in the electron density gradients and cause changes in the angle of arrival. But, one would expect them to be evident both in the components across and along the path, and there is no reason to expect them to be oscillatory.) The results presented here are interesting since they are in the path of totality, (but south of the centre line), and in fact the oscillations in γ_L decay in amplitude and γ_L returns to near its original value after a few cycles, as may be expected for a fully developed bow wave. But this dominant oscillation only in γ_L inside the shadow is unexpected. The only other angle of arrival measurements, to our knowledge, made during an eclipse⁶ showed that although in the F region a tilt was observed which was consistent with that expected from a consideration of the geometry of the eclipse path, no tilt or oscillation was observed in the normal E region or in an E_s layer which appeared 11 min after the maximum phase of the eclipse and lasted 9 min. These results, however, were not taken in the path of totality, but in a path that experienced only 0.72 obscuration at the maximum phase.

Fig. 1 Visible absorption spectra, measured at liquid nitrogen temperature, of representative diamonds following irradiation at room temperature with 2-MeV electrons to approximately the same dose ($\sim 10^{22}$ electrons m^{-2}). *a*, Relatively pure type IIB diamond, containing about 10^{24} m^{-3} B atoms—the damage level greatly exceeding this³⁶; $G/N = 18$. *b*, Type IA diamond with $4 \times 10^{26} \text{ m}^{-3}$ nitrogen atoms in small aggregates of donor binding energy $E_D \approx 4 \text{ eV}^{18}$, $G/N = 1.3$. *c*, Type IB diamond containing $\sim 5 \times 10^{24} \text{ m}^{-3}$ isolated substitutional atoms of $E_D \approx 1.7 \text{ eV}^{16}$; $G/N \ll 0.1$. For each diamond G/N gives the ratio of integrated strengths (wavenumber \times absorption) of the GR1 and ND1 zero phonon lines. The value for the type IA diamond differs from ref. 37 due to measurement in unfiltered tungsten light. The large linewidths in the type IA diamond are caused by its high nitrogen content³⁸.

previously except that the $25,410 \text{ cm}^{-1}$ (ND1) centre is postulated here to be the negative vacancy, V^- , and not the interstitial nitrogen atom as originally suggested². The reasons for this re-interpretation are as follows. After irradiation, all diamonds show the 'GR' absorption bands (Fig. 1, Table 1), which all occur at the same tetrahedral centre³⁻⁵. Since the GR bands are observable after high temperature annealing ($T > 1,200 \text{ K}$ in relatively pure specimens⁶), it is assumed they occur at the vacancy⁷ because during irradiation, the host interstitial in Group IV semiconductors seems to be highly mobile⁸⁻⁹. The lack of electron paramagnetic resonance (EPR) associated with the GR centre¹⁰ then implies a neutral vacancy V^0 or less likely multiple charged centres (V^{2+} , V^{4+} and so on).

The GR1 band is an E to T transition^{4,5} with its centroid at $(15,920 \pm 150) \text{ cm}^{-1}$ at 30 K. Many-electron LCAO calculations on V^0 predict a 1E or 3T_1 ground state, the two being almost degenerate¹¹⁻¹³. The first allowed transition from 1E , assuming it to be the ground state, is typically at $16,000 \text{ cm}^{-1}$ to a 1T_2 excited state. The excellent agreement with experiment on the irreducible representations of the states, their relative energies and their spin states supports the use of LCAO calculations rather than the alternative techniques which have not yet given even qualitatively correct energy level schemes^{14,15}.

Since the GR bands are the dominant product of irradiating relatively pure diamond (types IIA and IIB, see Fig. 1*a*), it seems that V^0 is the stable form of the vacancy in pure diamond.

It is important to consider the effect of irradiating type IB diamonds, whose dominant impurity is isolated substitutional nitrogen atoms with donor binding energies of about 1.7 eV (ref. 16).

Charge states of the vacancy in diamond

KNOWLEDGE of radiation damage processes in diamond has increased substantially in the past few years. I present here a concise summary of these data, and suggest that the $25,410 \text{ cm}^{-1}$ (ND1) absorption band occurs at a negatively charged vacancy. It will be shown that with this interpretation, the optical effects of radiation damage fall into a self-consistent pattern.

Optical studies of radiation effects in diamond have been carried out mainly in the visible spectrum following room-temperature irradiation with 1–2-MeV electrons. (For neutron and γ -ray effects see Clark *et al.*¹.) Table 1 summarises the results. The models given in the Table are as suggested

The GR bands are produced only weakly while the 25,410 cm⁻¹ (ND1) band, which also occurs at a T_d centre², is extremely strong (Fig. 1c). The simplest explanation is that the vacancies which must be produced by the irradiation are converted from V⁰ to V⁻ by charge transfer from the nitrogen donors: Loubser (personal communication) has observed a decrease in the EPR of these donors as the irradiation proceeds.

LCAO calculations, which seemed to be accurate for V⁰, predict that the first absorption band of V⁻ should occur between about 20,000 and 38,000 cm⁻¹ in an ⁴A₂ to ⁴T₁ transition¹¹⁻¹³. Experimentally the ND1 transition has been found to occur from an A to a T state², the centroid of the band being at (27,500 ± 200) cm⁻¹. The theoretical ⁴A₂ ground state implies an EPR active centre. No quantitative experimental study of this point has yet been made. A single isotropic line with *g* ≈ 2.0 has been observed in the three specimens inspected here, and also in measurements by Dyer and du Preez¹⁷. This EPR and the ND1 optical absorption show strikingly similar cyclic behaviour when the diamonds are subjected to alternate heating and bleaching cycles. However, Dyer and du Preez observed a decrease in the EPR signal and an increase in ND1 absorption after a 500 °C anneal in one specimen, suggesting that the absorptions arise at different centres, but these com-

parisons are not straightforward in view of the photochromic behaviour of the ND1 centre¹⁸. A detailed study of this EPR is required.

The assignment of the 25,410 cm⁻¹ (ND1) band to V⁻ produces two simplifications. First, reversible photochromic effects occur between the 13,495 cm⁻¹ (GR1) and 25,410 cm⁻¹ (ND1) bands even when the vacancy concentrations are ≈ 10⁻³ of the impurity content of the diamonds^{17,18}. If GR1 and ND1 occur at chemically indistinguishable sites a mechanism of charge transfer between defects of minor concentrations has to be designed. In terms of the present model, photoionisation of V⁻ (ND1) leads necessarily to V⁰ and hence GR1 absorption. Presumably the released electron produces the observed photoconduction¹⁹. Conversion of GR1 (V⁰) to ND1 (V⁻) by blue light¹⁸ (23,250 cm⁻¹ < *hν* < 25,400 cm⁻¹) is then seen to be by hole emission (V⁰ → V⁻ + h⁺), explaining the photoconductivity observed experimentally²⁰.

Second, in nitrogen-containing diamonds, thermal annealing destroys the 13,495 and 25,410 cm⁻¹ bands (GR1 and ND1) producing new optical bands (for example, at 15,690 and 19,865 cm⁻¹) depending on the form of nitrogen^{21,22}. Recent data imply that the new bands are formed when the nitrogen traps a vacancy²³⁻²⁵. In some experiments (ref. 23 and M. H. Nazaré, personal communication) the rate of growth of the new bands matches the destruction of GR1, in others^{22,26} it matches the removal of ND1. This is rationalised if both GR1 and ND1 occur at centres of the same chemical species (such as V⁰ and V⁻), and if we assume a charge redistribution can occur, if necessary, after trapping.

All our present optical data on irradiated diamond seem to be consistent with ND1 being V⁻. In principle, this model can be tested using a photo-Hall experiment to identify the carrier emitted when GR1 and ND1 centres are photoionised. The model predicts

$$h\nu + \text{GR1 (V}^0\text{)} \rightarrow \text{ND1 (V}^-\text{)} + h^+ \quad (1)$$

$$\text{and } h\nu + \text{ND1 (V}^-\text{)} \rightarrow \text{GR1 (V}^0\text{)} + e^-$$

In contrast, if GR1 and ND1 occur at chemically different sites, the same charge must be liberated when the GR1 and ND1 centres are photoionised, so that the observed cyclic processes can occur. The available data are not inconsistent with equation (1)²⁷.

The earlier suggestion² that the ND1 centre was an interstitial nitrogen atom was reached by arguing that defects in diamond have highly localised orbitals. In this limit it was thought reasonable to 'assume that it is unlikely that the effect of the presence of nitrogen (as an impurity in a diamond) is to produce charge compensation'². However, the data now available for type IB diamond (see Fig. 1c) show that the absorption strength of chemically stable defects like the GR1 centre is in fact strongly affected by the presence of the deep nitrogen donor (*E_D* ≈ 1.7 eV), an effect most likely to occur as a result of charge compensation.

Finally, the fate of the carbon interstitials, produced by the irradiation, seems to be that they are highly mobile, as in silicon²⁸, and become trapped at unknown crystal defects, producing complex EPR centres²⁹.

I thank A. M. Mainwood, C. M. Welbourn and J. H. N. Loubser for helpful discussions. Equipment was made available by de Beers Industrial Diamond Division Pty. Ltd and the Royal Society. This work was supported in part by the SRC.

Alkali cations and direct reduction of wustite

THERE are few reports^{1,2} on the direct reduction of wustite by carbon according to an autocatalytic mechanism, and none deal with its quantitative analysis in terms of any kinetic model. Eck³ has postulated that this mode of reduction is indicative of the increased role of processes such as diffusion and nucleation in the solid state, relative to the gasification of carbon by the Boudouard reaction—generally regarded as the rate-controlling step in the reduction⁴. We describe here a quantitative analysis of autocatalytic reduction in terms of the Prout-Tompkins⁵ mechanism for the growth of a product phase in the lattice of the unreacted phase. We derive a rate constant characterising the growth of the metallic phase and use it to evaluate the catalytic effects of small admixtures of alkali salts (ref. 6 summarises the literature on catalysed reduction).

Reduction of wustite in mixtures comprising precipitated red ferric oxide (Hopkin and Williams), spectrographic graphite (Union Carbide) and varying amounts of alkali salts (cation/Fe from 0.5% to 3.6% depending on catalytic effect) was studied at constant temperature by a Mettler Thermoanalyser. Samples were heated from room temperature at a rate of 25 °C min⁻¹ to the pre-selected temperature; simultaneous values of temperature, cumulative mass change (TG) and rate of mass change (DTG) were recorded.

The start of the wustite reduction (which always occurred after the reaction temperature was reached) was fixed at that value of mass loss which corresponds to the complete conversion of ferric oxide to wustite, assuming it to take place in a self-generated CO/CO₂ atmosphere in equilibrium with Fe₂O₃/Fe₃O₄. X-ray diffraction analyses of partially reacted samples confirmed the two-stage nature of reduction: Fe(III)—and Fe(III, II)—oxides were no longer detected when metallic iron appeared in wustite. The reductions were all carried to completion (as confirmed by stoichiometry and cessation of mass loss). Fractional conversion (α) of wustite to metallic iron was calculated from the TG data as fractional mass change values. Representative reduction curves are shown in Fig. 1.

The average mass change (29 measurements) was 38% relative to the starting mass of wustite. This suggests that >90% of wustite oxygen was abstracted as CO and that the composition of the reduction atmosphere lay closer to the Boudouard equi-

Fig. 1 Reduction of wustite to metallic iron by graphite in a dynamic argon atmosphere (flow rate 50 ml STP min⁻¹) at 960 °C in the presence of alkali catalysts. Alkalis were added as dry powders in the form of carbonates except for Rb (nitrate). TG data points were hand-read from a chart recording for the construction of reduction curves. Samples mass: 80 mg Fe₂O₃ + 15 mg C. Particle sizes: FeO ~ 1 µm (by scanning electron microscopy); graphite, 144 + 105 µm. Sample container: cylindrical alumina crucible (length, 20 mm; diameter 8 mm) resting on a Pt/Rh thermocouple junction. Sample loose-packed (bulk density ~ 0.5 g cm⁻³). Arrows indicate range of α for which the curves conform to equation (1).

librium (~ 98% CO) than to the wustite-iron-gas equilibrium (~ 70% CO).

We have estimated the rate constants characterising the reduction curves of Fig. 1 by fitting the curves in the range 0.2 < α < 0.95 to a modified form of the Prout-Tompkins equation for nucleation phenomena. The modification takes into account our experimental observation that the curves are in general not symmetric

$$\ln \frac{\alpha}{1 - (\alpha/2\alpha_i)} = k_3 t + \text{constant} \quad (1)$$

α_i is the value of α for which the rate of reduction (traced by the DTG curve) attains its maximum. k_3 is the so-called branching coefficient describing the appearance of nucleated iron by a

Fig. 2 Empirical relationship between the Prout-Tompkins branching coefficient k_3 and the Pauling ionic crystal radii of alkalis. Numbers in parentheses indicate the number of determinations of k_3 . Error bars denote the 95% confidence intervals (Student's *t* distribution). Line through data points is the least-squares fit. a (intercept) = 0.055 ± 0.025 , m (slope) = 0.195 ± 0.021 . Errors correspond to 1σ . The best-fit value of intercept is identified with the uncatalysed value of k_3 : 0.066 ± 0.016 min⁻¹ (four determinations).

chain mechanism. (See ref. 5 for the derivation of equation (1) when $\alpha_i = 0.5$.) In this interpretation of reduction, autocatalysis is essentially a consequence of the proportionality of the rate of reduction to the number of iron nuclei. Justification for this proportionality is provided by observations⁷ that the rate of abstraction of oxygen from wustite is much higher at the triple phase boundary wustite-iron-gas than elsewhere. We interpret deviations from the Prout-Tompkins mechanism for $\alpha < 0.2$ as resulting from the significant contribution made by the (unknown) initial nucleation law to the formation of metallic iron; derivation of equation (1) assumes this contribution to become negligible at some (low) value of α .

A summary of k_3 values derived by means of equation (1) (and recalculated by linear interpolation or extrapolation at cation/Fe = 2% to facilitate comparison) is given in Fig. 2. This also demonstrates a linear relationship ($r = 0.972$) between the catalytic effects of alkali cations and their ionic sizes.

We conclude first, that autocatalytic reduction of wustite yielding sigmoid-shaped reduction curves can be explained by invoking the Prout-Tompkins (branching chains) mechanism for the formation of metallic iron; and second, that alkali cations enhance the rate of this mechanism in direct proportion to their ionic sizes.

Pacific sea-surface temperature related to rain in California

CALIFORNIA is experiencing the worst drought in modern history, and there is much concern and speculation about future rainfall prospects. We recently succeeded in relating South Atlantic sea surface temperatures (SST) to rain in northeastern Brazil¹, and here we use similar methods to relate sea surface temperatures over the North Pacific Ocean to rainfall in California. We found December SST in the north-east Pacific off Washington to have a limited but definite predictive value, and to account for about 45% of the variation in California rainfall for the period February-April.

Namias has published several papers relating SST in the Pacific to atmospheric circulation². In our approach, aimed at obtaining a useful forecasting tool, we go directly from a contributory cause (SST) to an ultimate effect (rainfall), bypassing intervening physical processes. We justify this by the belief that rainfall is an integrator of the multitude of ocean-atmospheric interactions and processes that occur simultaneously on several scales of space and time.

We divided the rainy season into two parts, early rains (November-January), and the late rains (February-April). The months May-October are usually dry in California,

and when rains do occur they are influenced by factors apart from the normal November-April rains. We did not investigate the effect of SST on rains in May-October, although SST off Baja California is almost certainly related to the occurrence of September and October rains originating from decaying *chubascos*, or west coast Mexican hurricanes.

First, we established rainfall indices (RFI) for California. Rainfall is quite highly correlated among stations over most of the state. We chose three stations: Sacramento, Fresno and Los Angeles. All have long records, and are about equally spaced along the length of California. All three stations respond only to synoptic situations that are definitely wet, and receive little moisture from marginal situations. For November-April all three stations have high correlation with the November-April RFI, r being 0.90, 0.92 and 0.89, for Sacramento, Fresno and Los Angeles, respectively. To give each station equal weight in the index, multipliers of 0.86, 1.26 and 0.96, derived from 1930-60 mean annual rainfall values, were used for Sacramento, Fresno and Los Angeles, respectively. The RFI for a given period is the sum of weighted rainfall for that period, in millimetres.

Interestingly, for the period 1889-1972 there is no correlation between early and late rainfall indices. Kendall's parameter τ equal to -0.07 and r to -0.02, are not significant. Thus failure of early rains does not indicate that late rains will also be deficient.

Our SST values were mean temperatures developed by NMFS Pacific Environmental Group from ship observations assembled by the National Climatic Center. These values are means of all observations taken in a given 5° quadrant in a Marsden Square, during a given month and year. They have not been corrected for space or time bias, and it would be expected that correlations obtained from them would be improved if corrections could be made. We used monthly averages of available ship observations of SST in 5° quadrants, 1931-72, for the Pacific Ocean north of 15°N latitude. Ship reports for three Marsden Squares (90, 128, 130) were not conveniently available, so these areas were not considered. The area to the south-east of Hawaii and equatorwards of 15° is probably influential in California rainfall, but SST data there are too sparse for analysis. Elsewhere, data exist in most quadrants for most years, except 1941-46. In preparing our correlation maps, we used all values that were averages of four or more observations in a given month and quadrant, except a few extreme coldest and warmest values based on less than 10 observations were excluded.

In our work relating rain in Brazil to SST in the South Atlantic Ocean we found a slight warming trend of 0.0078 °C per yr for the period 1907-72, and had assumed that this warming was due to instrumental error resulting from evaporative cooling from bucket samples in early years, and heating by ships' engines in injection temperatures in later years. Removal of this trend improved correlations with rainfall. We had originally intended to adjust the North Pacific SST data for the same reason, but soon found that the trend was generally much larger and more variable in space and time than could be accounted for by instrumental factors. We therefore added an arbitrary 0.01 °C per yr before 1972, to compensate partially for the warming trend. Correlations obtained when temperatures are so adjusted are higher than when the raw data are used, which suggests that some degree of instrumental warming may be real.

We found little significant or useful correlation between Pacific SST and November-April rainfall, although there is a tendency towards negative correlation extending from the central Pacific to the region south-east of Japan. In general, the cold water there tends to make California rainy.

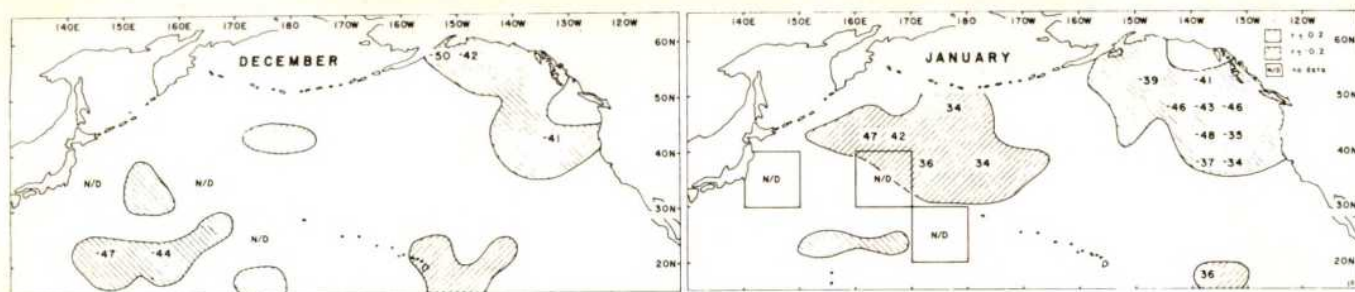

Fig. 1 Correlation between SST and November-January rainfall in California. Correlation coefficients plotted when significant above the 0.05 level.

We found no useful forecasting relation between Pacific SST and November-January rainfall, however, these rains are accompanied by negative correlation—cold water off the coast (Fig. 1). This substantiates Namias' view that warm water off the coast was involved in the 1976-77 winter drought in California³.

A useful forecasting relation seems to exist between SST and February-April rainfall. The situation begins with negative correlation (cold water) in the western and central parts of the Pacific in October. Later in November, December and January, positive correlation (warm water) appears in the Gulf of Alaska. This progresses southwards in February and March, while cold water remains a short distance out to sea (Fig. 2). The area of positive correlation in the north-east Pacific off Washington in December seems to offer the most promise in forecasting February-April rains. In this area MS 158-4 has a correlation coefficient (r) of 0.63 between December SST and February-April rainfall, significant above the 0.001 level. It seems that processes induced by cold water in the central and western Pacific in October, November and December,

when followed by warm water west of Washington in December, are favourable to February-April rains in California. This implies that SST gradient between the two areas is important although we found that this gradient does not yield correlation coefficients as high as using SST at MS 158-4 directly.

Mean SST values for a given month and quadrant contain real SST variations, as well as considerable noise due to non-random distribution of observations in space and time and to various instrumental errors. This noise can be reduced by using a median anomaly from three adjacent quadrants, using those quadrants most nearly aligned with the isotherms of SST. The median is a better measure than the mean because of the effect of extreme values on the mean. The three-quadrant median deviation is taken as the corrected deviation from normal for the central quadrant. Table 1 illustrates the derivation of corrected SST values for MS 158-4.

When monthly SST values in MS 158-4 are refined as stated above, by introducing data from adjacent quadrants, $r=0.68$ and $\tau=0.50$, both with massive significance. This

provides the basis for a February–April rainfall forecast using December SST (Fig. 3). Normal is defined as the mean for the 34 yr during the period 1931–72 when data exist in all three quadrants. When SST is normal, the rainfall forecast will be for 100% of normal, with 95% confidence limits between 10% and 190% of normal. If SST is 1°C above normal, the rainfall forecast is for 160% of normal, with 95% confidence limits between 65% and 250%. If SST is 1°C below normal the rainfall forecast is for 40% of normal, with 95% confidence limits between 0% and 135% of normal. The confidence limits are unfortunately wide, but probably reflect with reasonable accuracy the limits set by SST upon rainfall. Although imprecise, it is an improvement over a forecast based on climatic normals, which would be for 100% of normal with 95% confidence limits between 10% and 190% of normal, regardless of SST.

The τ value of 0.50 implies that the odds are three to

one that a change in rainfall will match the sign change in SST.

We believe that, early in the season, cold water in the central Pacific induces greater-than-normal troughing in the overlying atmosphere. This induces an increased frequency of south-westerly winds that push the SST isotherms northwards in the Gulf of Alaska. As winter advances the cold anomaly in the central Pacific is advected slowly eastward. Troughing in the atmosphere may likewise move eastward, and act to decrease the intensity of the surface subtropical high pressure cell off the California coast. The resultant decreased north-westerly winds along the coast allows a warm SST anomaly to form by decreased upwelling and by reduced southward flow of the California Current. The warm water moves southward, and then westward with the North Equatorial Current as the season advances, to create a positive anomaly of SST near Hawaii. Namias has shown that warm water in this area is important for

Fig. 3 February–April California rainfall indices (RFI) plotted against corrected December SST in Marsden Square 158–4. Normal SST is 9.04 °C and RFI is 459 mm. Years indicated are for SST. Second degree regression line with 95% confidence limits is shown.

California moisture⁴. Our speculation is tenuous, but we hope that other researchers will study the cause and effect relationships underlying what seems to be real correlation between SST and California rainfall.

We thank Jerome Namias for comments, Jim Canfield for cartography and Martha Raught for typing.

Direct measurements of secondary currents in river bends

FLUIDS flowing through pipes or channels can develop secondary currents. These are defined as currents which occur in the plane normal to the local axis of the primary flow. Their development in straight channels has been ascribed to anisotropic turbulence and the non-uniform distribution of boundary shear stress¹⁻³ but in meander bends they are generally caused by skewing of the flow³⁻⁵. Secondary currents distort the distributions of primary isovels and boundary shear stress from those expected in simple flows and, therefore, have important implications for bed and bank erosion and for resistance to flow. We report here measurements of longstream and cross stream velocities carried out across sections of a river perpendicular to the outer banks of several bends using an electromagnetic flow meter.

At meander bends fully developed secondary currents appear as a single flow cell, carrying surface water towards the outer

bank and bed water towards the inner bank⁶⁻⁹. Measurements in flumes^{10,11}, however, and in rivers^{12,13} have indicated the existence of a small cell of reverse circulation at the outer bank. A similar feature seems to exist in pipes¹⁴. As this reverse cell has been observed at single bends it is not connected with the reverse circulation of a relict cell from an upstream bend^{15,16}. Rozovskii¹¹ concluded that it is a wall effect, extending over a region of perhaps one or two depths from the bank, but negligible in bends with large ratios of width to depth. Hey and Thorne¹² proposed a new theory of secondary flow at bends, incorporating two cells in place of the classical single cell.

Identification of the outer bank cell in river bends has been based on only a few direct measurements of secondary flows^{12,13}. Because of a lack of suitable instrumentation, these measurements were relatively inaccurate and more detailed information is therefore required. The development of the electromagnetic flow meter has enabled such measurements to be made. This meter measures velocity in two directions simultaneously and so enables the components of horizontal flow to be defined. Measurements can be made to within 1 cm s^{-1} (refs 17 and 18).

In this investigation, measurements were made with an electromagnetic flow meter along sections perpendicular to the outer banks of several bends. The meter was positioned to measure the longstream velocity (parallel to the outer bank) and the cross stream velocity (perpendicular to the outer bank.) These are not necessarily the primary and secondary velocities but the following theory allows calculation of those components.

Secondary currents at any vertical through the flow are defined to occur in the plane normal to that containing the mean primary velocity vector at that vertical. It is assumed that in steady conditions, the average secondary flow in the plane is zero, that is, the secondary discharge in one direction is balanced by the discharge in the other. The longstream and cross stream velocities (those to which the electromagnetic meter responds) are defined by \mathbf{u} and \mathbf{w} respectively. The resultant velocity \mathbf{q} at any depth y is defined to be at a horizontal angle θ to the longstream axis so that

$$u = q \cos \theta \quad (1)$$

$$\mathbf{w} = \mathbf{q} \sin \theta \quad (2)$$

The mean primary velocity U at the vertical is at the fixed angle $\mathbf{1}$ to the longstream axis. $\mathbf{1}$ defines the vector of the

primary flow so the primary velocity U_p at any depth is found by resolving in that direction

$$U_p = q \cos(\theta - \phi) = u \cos \phi + w \sin \phi \quad (3)$$

The secondary velocity U_s is obtained by resolving in the plane normal to that containing the primary velocity vector

$$U_s = q \sin(\theta - \phi) = w \cos \phi - u \sin \phi \quad (4)$$

ϕ is unknown but is found by integrating the secondary

as far as was necessary to establish the presence of the main cell (Figs. 2 and 3).

The single classical cell does not always continue to the outer bank. Reverse cells are evident up to one depth from the bank at Rickety Bridge Bend and at Maes Mawr Bend. This pattern is reflected in the distortion of the primary isovels. However, the outer bank cells do not appear at Llandinam Bend.

The outer bank cells probably result from interaction of the main cell with the outer bank. The flow of this cell has a component perpendicular to the bank and, in an ideal fluid, the boundary streamlines of this component would follow exactly the water surface and the boundary of the channel. In a real fluid, this is not possible since it requires an infinite acceleration

Fig. 1 Primary and secondary velocities at Llandinam Bend—River Severn. Channel width 10 m; radius of curvature 75 m; bend arc angle 62°; discharge 1.1 m³ s⁻¹.

velocities over the depth, d . As their mean is defined to be zero,

$$\int_0^d q \sin(\theta - \phi) dy = 0 \quad (5)$$

so that

$$\tan \phi = \frac{\int_0^d q \sin \theta dy}{\int_0^d q \cos \theta dy} = \frac{\int_0^d w dy}{\int_0^d u dy} \quad (6)$$

w and u are the velocities measured by the electromagnetic meter. Substitution of the value of ϕ into equations (3) and (4) allows the secondary and primary velocities at any depth to be calculated.

Measurements were made at three bends on the Upper River Severn. Llandinam Bend is a single bend at a shallow section of channel. Rickety Bridge Bend is a slight bend just downstream from a riffle which directs the flow strongly against the outer bank. Maes Mawr Bend is a conventional meander bend, on a pool and downstream of a shallow reach.

A complete survey was made at Llandinam Bend at a low discharge and this shows the classical cell across the whole channel (Fig. 1). At the other sites, velocity profiles were taken at progressively greater distances from the outer bank but only

at the junction of bank and water surface, so a breakdown of the ideal pattern is expected.

The occurrence of the reverse cells seems to depend on the form of the bank. They do not occur where the bank shelves but do where the bank is perpendicular to the water surface. This is verified by several other surveys made at high and low discharges and at shelving and steep banks at Maes Mawr bend. Where the outer bank is steep, the junction

Fig. 2 Primary and secondary velocities at Rickety Bridge Channel—River Severn. Channel width 8 m; radius of curvature 50 m; bend arc angle 50°; discharge 1.7 m³ s⁻¹.

Fig. 3 Primary and secondary velocities at Maes Mawr Bend—River Severn. Channel width, 21 m; radius of curvature, 70 m; bend arc angle, 38°; discharge $9 \text{ m}^3 \text{ s}^{-1}$.

of bank and water surface (seen in section) corresponds to a stagnation point. At this point, water would be expected to pile up and it is possible that the resulting upwelling at the surface, combined with the weight of the superelevated water, could trigger a more general reversal of secondary flow in the region of the bank. This process might be aided by the local surging of flow which results from the passage of turbulent eddies.

If this theory is correct, the strength of the outer bank cell should be proportional to the component of flow towards the outer bank. This seems to be confirmed because the cell at Rickety Bridge Bend, where the flow is directed against the bank, is stronger than at Maes Mawr Bend.

Direct measurements of outer bank cells confirm that the classical cell oversimplifies the pattern of secondary flow in some river bends. This has important repercussions for the evaluation of flow resistance, the distribution of boundary shear stress, the movement of bed load and thence bank erosion and meander migration.

Prehistoric dental calculus gives evidence for coca in early coastal Ecuador

LOS CERRITOS, a late Chorrera (Engoroy) cemetery on the Santa Elena Peninsula of Ecuador yielded artefacts and radiocarbon assay which indicate that use of the site began about 840 BC and continued for several years within the Late Formative¹. The human skulls from the site are of particular interest because many showed heavy accumulations of supragingival dental calculus (tartar), which contrast with the relatively slight calculus accumulations on the teeth of skulls recovered from the earlier Valdivia (3000–1500 BC) site of Real Alto², also on the Santa Elena Peninsula. We argue here that the heavy calculus accumulations are the result of habitual, secular coca chewing in late Chorrera times. This diagnosis, in turn, supports the hypothesis of prehistoric trade in coca, probably in exchange for mollusc shells, with inhabitants of the eastern Andean slopes.

Of 27 adult human skulls from Los Cerritos with dentitions sufficiently intact to be evaluated, 17 had calculus deposits which ranged from slight to extreme (Table 1). This scale was devised to accommodate the range of variation in the material; even 'slight' would be considered heavy by modern standards.

According to ethnographic accounts^{3–5}, coca leaves were commonly chewed with lime in western South America. The lime is responsible for the dental deposits. Mehta *et al.*⁶ noted that heavy calculus in modern India correlated with chewing betel with lime. Leigh⁷ reported large dental accretions from prehistoric Guam, which he attributed to the habit of chewing betel nut with lime. He concluded that similar deposits from prehistoric Peru resulted from coca chewing⁸. Moodie⁹ also observed excessive calculus among pre-Columbian Peruvians. In the prehistoric examples, as in the Chorrera material, the deposits were on the buccal tooth surfaces of both maxilla and mandible, which is in accord with the practice of holding the quid between the cheek and teeth. In contrast, the sites most affected in modern populations are those near the openings of the salivary ducts—the lingual surfaces of mandibular incisors and the buccal surfaces of maxillary molars.

Lime has been implicated as an aetiological factor in dental deposits, but the nature of the deposits is uncertain. Mehta *et al.*⁶ called the deposits calculus, but Leigh⁸ referred to them as lime. The chemical composition not only provides an accurate description of the pathology, but can reveal clues about the mechanism and conditions of the depositions. Six samples of dental accretion from six Los Cerritos skulls were subjected to elemental and X-ray diffraction analysis. The samples were cleaned only by dry-brushing.

The major and minor elemental analysis of the deposits was performed by standard X-ray fluorescence techniques as developed by Rose *et al.*¹⁰. To approach a total composition of the material mean values are reported in Table 2 as the percent of oxides, even though the elements actually occur in mineral form. The sum of the components is less than

Table 1 Calculus deposits on the teeth of adult human skulls from Los Cerritos

Extent of accumulation	Probably male	Probably female	Sex indeterminate
Extreme	1	0	0
Very heavy	4	0	0
Moderately heavy	5	2	0
Slight	1	4	0
None	2	7	1

100% because very limited sample sizes precluded determination of carbon dioxide, moisture, and ignition loss.

X-ray diffraction patterns of each sample revealed a poorly-crystalline apatite-like phase representing hydroxyapatite, $\text{Ca}_{10}(\text{OH})_2(\text{PO}_4)_6$, a major component of calculus¹¹⁻¹³. Considerable quartz was also present, together with some calcium silicate, $\text{Ca}_3\text{Si}_2\text{O}_7$, or calcium aluminium silicate, $\text{CaAl}_2\text{Si}_2\text{O}_8$. The similarity of the compositions indicates that the teeth were in contact for long periods with ground water from which silica precipitated within the relatively porous calculus structure.

Table 2 Major and minor elemental analysis of dental deposits

Element	% of oxides
SiO_2	40.02 ± 10.78
Al_2O_3	6.17 ± 2.02
CaO	26.01 ± 8.88
K_2O	0.42 ± 0.15
MgO	2.02 ± 0.87
Na_2O	1.08 ± 0.56
Fe_2O_3	3.96 ± 1.20
TiO_2	0.77 ± 0.21
P_2O_5	16.13 ± 5.33

Values are means \pm s.d. for six samples.

Brushite, $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, and octacalcium phosphate, $\text{Ca}_8\text{H}(\text{PO}_4)_3 \cdot 2\text{H}_2\text{O}$, which are two crystalline forms known to occur in some calculus samples¹¹⁻¹³, were not discernible. It was not clear whether magnesium whitlockite, $(\text{Ca}, \text{Mg})_3(\text{PO}_4)_2$, another crystalline form found in some calculus, was present in any of the samples since certain major diffraction peaks for this substance fall in the same region as those characterising hydroxyapatite which was present. Insufficient sample sizes precluded fluoride analyses.

The presence of hydroxyapatite plus percentages of calcium and phosphorus similar to those reported for calculus¹¹⁻¹⁴ suggest, but do not confirm, that the accretions were originally laid down as dental calculus, not as lime or other simple calcium salts. Variations in the relative ratios of calcium, phosphorus, and magnesium indicate that some degradation has taken place on the calculus itself. This, together with the postmortem contamination, indicates that preservation of the material has been affected by environment, but not sufficiently to invalidate the basic conclusion.

The magnesium concentration in the samples was higher than that reported for modern calculus¹¹⁻¹⁴ but is compatible with the chewing of coca leaves since magnesium is a constituent of chlorophyll and a cofactor in some plant enzymes.

Since the lime was responsible for the deposits, the possibility that the people were chewing tobacco with lime cannot be ruled out altogether. Nevertheless, there is circumstantial evidence which argues in favour of coca use. In South America the historic distribution of chewing tobacco with lime was much more restricted than that of chewing coca with lime³. Furthermore, in the early historic period tobacco was used pre-eminently in ritualistic context whereas coca use was commonly secular and hedonic³. The huge calculus deposits imply habitual and, therefore, secular use. At Los Cerritos calculus deposits were more severe among males than females, suggesting that coca consumption by males was either more frequent or began at an earlier age.

Cultural evidence for the chewing of coca in coastal Ecuador appears as early as Valdivia times. Small ceramic lime pots have been found at Valdivian sites¹⁵, including Real Alto. In addition, a figurine recovered from the Valdivia-type site clearly depicts a quid in the cheek of a woman¹⁵.

Why, then, do the skeletons from Real Alto not show heavy deposits on the teeth? Presumably coca chewing expanded from a restricted, probably shamanistic, role in the Early Formative to a more popular, secular role in the Late Formative.

Since the climate of the Santa Elena Peninsula precludes the growing of coca, which thrives on the well-watered eastern slopes of the Andes, coca must have reached the coast by trade. Although there is evidence for trade routes as early as the Valdivia period^{16,17} commerce had become much more extensive by late Chorrera times. Paulsen¹⁸ presents evidence for the export of thorny oyster and conch shells from the Ecuadorian coast to the sierra beginning as early as 2800 BC. She concludes that the limited trade of the Early Formative had expanded to the Peruvian Andes by the first millennium BC. We propose that increased importation of coca to the south coast of Ecuador accompanied expanded exportation of mollusc shells to the sierra. In times of limited trade imported items would be at a premium and probably reserved for religious or curing purposes; expanded trade would make the exotic item, coca, available to a wider segment of the population for temporal use, in much the same manner as it is used by modern Andean peoples.

We thank C. Zevallos M. and R. Parducci M. for permission to study the Los Cerritos skulls and to take calculus samples; J. Zeidler for obtaining the samples, and D. B. Shimkin, J. G. Marcos, and D. W. Lathrap for valuable advice.

High levels of cadmium in Atlantic seabirds and sea-skaters

THE possibility that cadmium may be an environmental pollutant has caused concern because it has toxic effects on many animal species including man, rat, rabbit, chicken, quail, and pigeon¹⁻⁴. The occurrence of cadmium in wildlife is not unusual and samples of marine species taken from around the British coast contain low levels (less than 0.5 mg per kg in fish and less than 2 mg per kg in most shellfish); however, levels of up to 93 mg per kg were present

in limpets, *Patellasp.*, collected from areas of natural mineralisation or industrial sources of cadmium⁵. Seabirds generally contain higher residues than marine invertebrates. For example, Anderlini *et al.*⁶ examined the amounts of nine metals in the livers of seven Antarctic and Pacific seabird species and noted that the maximum mean cadmium residue occurred in 10 ash petrels *Oceanodroma homochroa* collected from their breeding grounds in California (mean residue was 53.2 ± 20.5 mg per kg). Parslow *et al.*⁷ found up to 22.3 mg per kg dry wt cadmium in livers of eight puffins *Fratercula arctica* collected live from various British breeding colonies. It was suggested that pelagic birds might contain higher residues than coastal living species because a single fulmar *Fulmarus glacialis* examined by them contained 159 mg per kg cadmium. Anderlini *et al.* concluded that there was a correlation between increased concentration of cadmium in birds and exposure to industrial influences. Parslow *et al.* did not attempt to explain the residues they found in puffins, but Bourne⁸ concluded that individual birds were becoming increasingly contaminated through feeding near areas of local pollution around the British coast. It is debatable whether cadmium should be regarded as a pollutant to seabirds. We report here the occurrence of cadmium residues in the tissues of apparently healthy, breeding seabirds which are considerably higher than any previously found. More important, we conclude that the cadmium has a natural rather than an industrial origin, since we have found high cadmium residues in a marine insect, *Halobates*, which is widely distributed in tropical regions far from sources of industrial cadmium. This insect is only one example of the sources from which birds obtain their cadmium residues.

Table 1 Cadmium residues in individual St Kilda seabirds

Species	Sex	Cadmium concentration (mg per kg dry wt)	
		Liver	Kidney
Fulmar <i>Fulmarus glacialis</i>	1* ♂	9.1	46.7
	2* ♀	50.1	184
	3 ♂	7.7	32.8
	4 ♀	49.4	240
Manx shearwater <i>Puffinus puffinus</i>	1 ♂	26.0	133
	2 ♀	39.9	231
	3 ♂	14.6	67.0
	4 ♀	15.6	113
Puffin <i>Fratercula arctica</i>	1 ♂	18.9	109
	2 ♀	14.1	75.1
	3 ♂	29.4	125
	4 ♀	57.0	68.5
Leach's petrel <i>Oceanodroma leucorhoa</i>	1 ♂	21.5	128
	2 ♀	20.6	80.0
	3 ♂	9.2	30.2
	4 ♀	14.4	52.9
Storm petrel <i>Hydrobates pelagicus</i>	1 ♂	20.8	37.7
	2 ♀	26.5	36.7
	3 ♂	2.4	14.6
	4 ♀	1.8	16.0
Razorbill <i>Alca torda</i>	1 ♂	1.4	18.2
	2 ♀		

Birds were killed by exsanguination and their tissues immediately frozen using solid CO₂ and kept below -20 °C until analysed for heavy metals. Metal analyses were performed by atomic absorption spectroscopy after tissues had been digested with concentrated nitric acid. Parentheses show birds known to be paired.

*Birds known to have an egg. Fulmars 3 and 4 were prospecting birds not yet ready to breed. All other subjects were thought to be breeding but this could not be confirmed due to inaccessibility of the nest site.

|| This bird had a shelled egg in the oviduct.

In June–July 1976 21 seabirds representing six species were collected, under licence, at a major breeding colony on St Kilda, a remote island group 80 km west of the Outer Hebrides, Scotland. All the animals were apparently healthy and unaffected by the metal levels they carried (Table 1). In all species, residues were higher in the kidney than in the liver, as in cadmium-contaminated humans¹. Cadmium residues were considerably higher in the pelagic species (shearwaters, puffins, and petrels) than in the razorbill, which feeds in the region of the continental shelf throughout the year^{9,10}. Since the pelagic species on St Kilda are unlikely to be exposed to industrial cadmium, it seemed possible

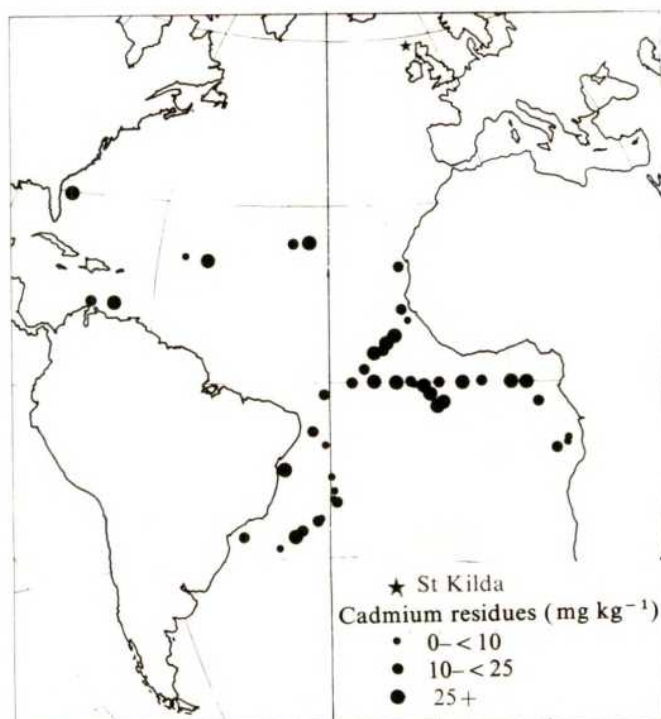

that there might be important sources of cadmium in the open ocean.

Leatherland *et al.*¹¹ examined a range of plankton organisms and their predators, although very small samples were involved. They found appreciable levels of cadmium in some species, the maximum being 13 mg per kg dry wt in the decapods *Systellaspis debilis* (four examined) and *Ophophorus* sp. (two examined). Plankton samples are usually of a variably mixed species composition and it is not easy to isolate a single species from a wide range of localities to check for geographical variations in cadmium content.

Sea-skaters of the genus *Halobates* (Gerridae: Heteroptera) are pelagic marine insects. They live at the sea surface and feed on zooplankton trapped at the air–sea interface. Relatively high cadmium contents have been detected in *Halobates* from various parts of the Pacific Ocean, and these may reflect correspondingly high cadmium levels in the waters where the samples were collected¹². It seems unlikely that the high cadmium levels detected in the sea-skaters resulted from atmospheric pollution, as no cadmium was detectable (< 5 mg per kg dry wt) in another gerrid, *Rheumatobates aestuarius*, collected from coastal mangrove lagoons in the Gulf of California, close to the area where *Halobates* was found at sea with very high cadmium levels (up to 200 mg per kg dry wt)¹². Since these insects are widely distributed in the oceans and single-species samples can be obtained over a large area, their cadmium contents can indicate the distribution of this heavy metal in the surface layers of the ocean.

Samples of *Halobates micans* were obtained from tropical areas of the Atlantic Ocean. These were rinsed of all foreign matter with acidified distilled water, digested in concentrated nitric acid and then analysed for cadmium using atomic absorption spectrophotometry. The distributions of residues in the samples were not uniform (Fig. 1) but there was no pattern suggesting pollution. The mean concentration in 111 samples was 22.7 ± 3.1 mg per kg dry wt, ranging from 0 to 309 mg per kg (in a sample from the Gulf of Guinea). In many instances several samples were collected at one

Fig. 1 Cadmium content of *Halobates micans* collected from 47 sites along survey routes in the Atlantic; the species is confined to warmer waters. In cases when more than one sample was collected from the same site the highest value has been plotted. St Kilda was the collecting locality for the seabirds analysed for cadmium (Table 1). Sources of *Halobates* samples and acknowledgments are given by Cheng¹².

site and in Fig. 1 maximum values are depicted; the mean for these was 30.5 ± 6.7 mg per kg ($n = 47$).

The concentration of cadmium in the ocean varies little from the depths to within 0.5 km of the surface layer, but declines rapidly near the surface, conceivably as a result of incorporation into living organisms¹³. Some of the areas where the higher cadmium residues occur, for example, off the coast of West Africa, have little industrial activity, but have upwelling ocean currents of cold water which bring to the surface nutrients, and possibly cadmium too. Areas of ocean upwelling are known to be important wintering locations for pelagic seabirds, because they are rich feeding grounds, and it is likely that the birds accumulate at least some of their residues in these places. The Manx shearwater spends the contranuptial season off the coast of South America, while the storm petrel winters off South Africa and Leach's petrel very widely in the tropics; puffins ringed on the western coast of Britain have been recovered south of the Straits of Gibraltar but the precise wintering grounds remain to be defined¹⁴. We cite the *Halobates* data as an indication of the widespread occurrence of cadmium in tropical waters. It is doubtful whether many seabirds take large quantities of *Halobates* though the phoenix petrel *Pterodroma alba* and blue-grey noddy tern *Procelsterna cerulea* have been proved to eat them in the Pacific^{15,16}. We might, therefore, expect these insects to be among the sources from which such birds as storm petrels could obtain cadmium.

We conclude that the high cadmium concentrations found in seabirds originate from natural sources, rather than from industrial activity, and that the birds, having evolved in an ecosystem containing cadmium, have developed, through natural selection, mechanisms which enable them to tolerate this metal. One such mechanism, now being investigated, involves production of a metal-binding protein which has been identified in the fulmar—it has many of the properties of metallothionein.

We thank P. Freestone and L. A. Sheppard for help with the heavy metal analyses.

Pectolytic anaerobic bacteria cause symptoms of cavity spot in carrots

CAVITY spot, a disease which causes considerable damage to the mature storage roots of carrots in several countries including the United Kingdom and the United States¹, has been reported to be caused by calcium deficiency, either actual or induced by excessive potassium levels in the soil². We have examined diseased carrots in

East Scotland since 1966 and have been unable to confirm the relationship with calcium levels. Evidence reported here indicates that pectolytic bacteria of the anaerobic genus *Clostridium* are the cause.

In the light of observations that the incidence of cavity spot was greatest in wet seasons on poorly drained land, and that more roots had lesions in waterlogged than in freely drained pots, the effect of restricting aeration to roots was investigated. Carrots were grown in plastic pots containing UC sand-peat compost (a mixture of three parts peat to one part coarse sand, formulated at the University of California) and when the crown diameters were greater than 20 mm, the compost surface was sealed with paraffin wax (melting point 55 °C). Roots of similar size were also lifted from the field, washed carefully and transplanted to similar pots. The pots were placed in trays containing 25 mm of water and kept in a controlled environment cabinet at 20 °C with an 18-h daylength of 12,000 lx. Analyses of gas composition in the compost (gas chromatogram, Pye model 106, MS 5A column, length 152.4 mm, oven temperature 100 °C) indicated that anoxic conditions developed within 48 h. After 5 or 6 d the wax was removed and the pots were returned to the glasshouse bench. Characteristic lesions were observed 3 weeks later. The proportion of roots affected was greatly increased when soil from a field outbreak was added to the roots before sealing. For example, the percentage of roots with lesions in an experiment in which all pots were sealed and supplemented with field soil or autoclaved field soil, or not supplemented, were 72, 28, and 24% respectively ($P < 0.001$ on contingency analysis).

Because there was evidence of a heat-labile factor in field soil and because no fungi or bacteria which were pathogenic on re-inoculation had been isolated by conventional techniques, isolations and subsequent inoculations were carried out under hydrogen in McIntosh and Fildes anaerobic jars fitted with palladium catalysts. Using a reducing medium with a pectate layer³, we isolated pectolytic bacteria at 25 °C from lesions formed on roots in sealed pots supplemented with field soil. Isolates were repeatedly sub-cultured from single colonies on streaked pectate plates and when grown in liquid basal medium anaerobically and inoculated to carrots, lesions identical to those caused by the soil supplement developed in sealed but not in open pots. The bacteria were recovered from these lesions by anaerobic culture.

Similar bacteria were obtained from several fields where cavity spot had occurred by inoculating carrot disks with about 1 g soil, and they were also recovered from some natural lesions incubated, like the disks, in anaerobic conditions. The colonies were cream coloured and the bacteria grew rapidly in anaerobic conditions at 25 °C producing a plaque in the pectate layer of up to 20 mm diameter in 2 d. Pectolysis on media and on carrot disks was still evident at 10 °C and no growth occurred on agar or on carrot disks in air. The bacteria were gram negative rods, 2.8–5.2 × 0.6–0.8 nm, which produced sub-terminal ovoid endospores, 1.4–2.4 × 0.8–1.0 nm. Gelatin was not liquified within 7 d at 25 °C. The organism was identified as a member of the genus *Clostridium*⁴, although results of further tests did not agree with those of any described species.

Cavity spot often occurs on poorly drained, compacted soils and it is most common after heavy rainfall in midsummer when the soil biomass and the high root population of carrots grown for canning may deplete oxygen more rapidly than it can be replaced by diffusion from the atmosphere. In these conditions it is suggested that the anaerobic bacteria described here may initiate cavity spot lesions. Pectolytic *Clostridium* spp. have been implicated in the rotting of potatoes in storage but they have not been associated previously with a field disease syndrome.

We thank Mr R. A. Fox and Dr M. C. Pérombelon for helpful suggestions and Dr G. Hobbs for examining isolates of the bacterium.

Carcinogenic activity of hexachlorobenzene in hamsters

HEXACHLOROBENZENE (HCB), has been widely used as a fungicide, is a contaminant of various pesticides including DACTHAL and pentachloronitrobenzene, and is also a by-product in the manufacture of many chlorinated hydrocarbons (in the United States probably more than 2×10^6 pounds of HCB are produced annually¹). In Turkey, HCB was the causative agent in a severe outbreak of porphyria cutanea tarda symptomata involving several thousand people between 1955 and 1959 (refs 2-4). In spite of the ban of HCB in 1959, symptoms of disease due to this toxic porphyria have persisted for a long time^{5,6}. The aim of present studies was to determine the chronic toxicity of HCB after prolonged oral administration and we report here that HCB is carcinogenic in hamsters.

Six-week-old Syrian golden hamsters from the Eppler colony were used. They were fed *ad libitum* for life a diet containing 50, 100 and 200 parts per million (p.p.m.) HCB. The HCB was more than 99.5% pure (BDH, England). Dosage regime and experimental design are shown in Table 1. At 50 weeks of age, 71% of the treated animals were alive, a survival rate

Table 1 Dosage regime for HCB in hamsters

Group	No. of animals		Concentration of HCB in diet (p.p.m.)	Duration of treatment	Calculated daily intake (mg kg ⁻¹ d ⁻¹)
	F	M			
Control	40	40	0	Lifespan	0
Low	30	30	50	Lifespan	4
Medium	30	30	100	Lifespan	8
High	60	59	200	Lifespan	16

comparable with that of the controls. After 70 weeks, a shorter lifespan occurred in both females and males treated at the highest dose level of HCB; compared with the controls, males treated at 200 p.p.m. HCB showed a marked weight reduction. Table 2 gives cumulative data on the tumour incidence at each dose level. The percentage of tumour-bearing animals (TBA) varied, with controls showing a 10% incidence and hamsters treated at 200 p.p.m. HCB, a 92% average incidence. There was, therefore, an obvious difference relative to treatment. The average number of tumours per hamster and the percentage of hamsters with more than one tumour also showed a dose-response relationship.

All 15 thyroid tumours found were alveolar adenomas and were present only in treated animals. There was a significant increase ($P < 0.05$) in occurrence of these tumours in males treated at 200 p.p.m. HCB, when compared with male controls.

No hepatomas were seen in the control group. In the HCB-treated animals, the incidence increased from 46% in the group treated at 50 p.p.m. to 85% in hamsters receiving 200 p.p.m. HCB. No hepatoma metastases were found. The first hepatoma (with multiple nodules, the largest in diameter being 7 mm) occurred in one female hamster that died after 18 weeks of treatment.

Liver haemangioendotheliomas were also observed only in the HCB-treated group. The highest and significant incidence occurred in the group treated at 200 p.p.m. HCB, consisting of 11.6% of females and 35% of the males. Three of the haemangioendotheliomas in these animals metastasised. A few haemangioendotheliomas were observed in the spleen.

Among other tumours, an increased incidence of adrenal neoplasms occurred; however, no clear dose-response relationship was shown, nor was there a significant difference between the groups.

The results indicate the carcinogenicity of HCB. In the case of other known carcinogens, such as dimethylnitrosamine, vinyl chloride, 2-acetylaminofluorene and 2-naphthylamine, there is a wide spectrum of carcinogenic activity in different tissues and species, including the hamster. In our present experiment, doses of HCB ranging from 50 to 200 p.p.m. resulted in a significant induction of hepatomas, haemangioendotheliomas and thyroid adenomas. Further, an increased number of tumour-bearing animals and of tumours per animal was noted, as were a shortened lifespan and a reduced latency period for onset of liver tumours. These effects may indicate that HCB behaves like certain carcinogens shown to have multipotential activity.

A purely quantitative approach indicates that an intake of 4-16 mg kg⁻¹ d⁻¹ of HCB in our hamsters was within the range of the estimated quantities accidentally consumed by the Turkish people for several months at a time, resulting in severe toxic porphyria⁴.

In a study conducted in Louisiana, in 86 persons who resided in an HCB-contaminated area, the mean HCB concentration in plasma samples was 0.0036 p.p.m. (ref. 7). In yet another investigation, farm workers occupationally exposed to HCB-contaminated DACTHAL had blood HCB concentrations averaging 0.040 p.p.m. but there was no evidence of porphyria in this group⁸. It must, however, be stressed that with Burns' two cross-sectional epidemiological studies^{7,8}, it would have been very difficult to demonstrate the carcinogenicity of HCB.

The extrapolation of the present experimental results to man is not possible without considering all available data on the biological effects of HCB. In this sense, we believe there is urgent need to obtain epidemiological information to evaluate the relevance of the experimental studies.

Effect of aspirin administration on retinoic acid toxicity in mice

THIS study was designed to provide an indirect assessment of the possible role of prostaglandins in retinoid intoxication. If the symptoms of retinoid toxicity are mediated by prostaglandins, an inhibitor of prostaglandin synthesis should ameliorate the symptoms of sublethal intoxication and perhaps even increase the lifespan of mice treated with lethal doses of retinoids. The observations reported here indicate that aspirin can antagonise the toxic effects of retinoic acid.

Sporn *et al.*^{1,2} have presented information on the biological activity of a number of retinoids (vitamin A analogues). Retinoids seem to influence differentiation of epithelial cells in several tissues to the extent that in certain test systems, they prevent or reverse malignant transformation of epithelial cells exposed to known carcinogens¹. This activity holds promise for the 'chemoprevention'² of cancer in man. Since chemoprevention will involve use of a drug by individuals who have a greater than average chance of developing cancer but who may be healthy otherwise, the acceptability of retinoids may depend on their toxicity. Excessive doses of retinol or all-*trans*-retinoic acid (RA) produce a hypervitaminosis A syndrome in man and experimental animals^{3–6}. Hixson and Denine⁶ suggested that this syndrome might be more appropriately referred to as retinoid intoxication, since many of the retinoids exhibit similar side effects, including headache, vomiting, pruritus, skeletal pain, and bone resorption^{3–5,7}.

The mechanism of retinoid toxicity has been open to question^{1,2}, but the syndrome suggests a possible mediator. Headache^{8,9}, vomiting⁹, pruritus⁸, skeletal pain^{10,11} and bone resorption^{12–14} are common symptoms of retinoid intoxication and prostaglandin activity. Hypothetically, the symptoms of retinoid intoxication may be mediated by prostaglandin production. As a preliminary test of this hypothesis, we have treated mice with a combination of aspirin and toxic doses of RA. Vane⁸ demonstrated that aspirin inhibits prostaglandin production, and subsequent studies have confirmed his conclusions^{15,16}. Since bone thinning (resorption) and occurrence of fractures provide a dose-dependent indication of retinoid intoxication in mice⁶, we have used this endpoint and the incidence of mortality to demonstrate that aspirin protects mice from retinoid intoxication.

To produce retinoid intoxication in mice, RA (30 mg kg⁻¹) was administered intraperitoneally (i.p.) daily for 21 d

(Q1D×21). This dose approximated the LD₅₀ obtained previously with this schedule in our laboratories^{6,17}. RA was suspended in an aqueous solution of 8% Cremophor EL (Sigma) and 10% propylene glycol; these suspensions were protected from light. Aspirin (ASA) was suspended in a mixture of physiological saline and 0.3% hydroxypropyl cellulose. Sixty adult Swiss mice weighing approximately 24 g (range: 21–27 g) were distributed into three experimental groups of 20 mice each (10 male, 10 female). Drugs were administered according to individual body weight as follows: RA only, 30 mg kg⁻¹ i.p., Q1D×21; ASA only, 150 mg kg⁻¹ by mouth (p.o.), Q1D×21; RA 30 mg kg⁻¹ i.p. plus ASA 150 mg kg⁻¹ p.o., Q1D×21. Mice were weighed twice weekly and X-rayed on treatment days 1, 8, 15, and on the day after the last treatment. X-ray films were evaluated weekly to determine the number of fractured bones per mouse. During the treatment period, including the day after last treatment, deaths per total mice (group) were: 10/20 (RA), 1/20 (ASA), and 0/20 (RA+ASA). This experiment was repeated: 60 mice weighing approximately 26 g (range: 22–30 g) were distributed and treated as before, except that these mice were not X-rayed on treatment day 1. In this experiment, deaths per total mice (group) were: 7/20 (RA), 0/20 (ASA), and 3/20 (RA+ASA).

The frequency of deaths and the frequency of fractures among survivors on days 8, 15, and one day after last treatment were arranged as a contingency table for each experiment. Since no fractures occurred in ASA-treated mice, they were excluded. Chi-square analysis¹⁸ indicated that the data from the two experiments were sufficiently homogeneous to justify pooling them. The pooled data (Table 1) were then tested for statistical significance¹⁸. The difference in mortality between the RA group (17/40) and the RA+ASA group (3/40) was significant ($P < 0.001$) on the day after last treatment. On day 15, the number of mice with three or more fractures was significantly greater in the RA group than in the combination group ($P < 0.05$); no other significant differences were observed and there seemed to be no sex differences. Differences were apparent between the general condition of mice in the RA group and the RA+ASA group on the day after last treatment. Loss of body weight, for example, is characteristic of sublethal retinoid intoxication.

Data presented in Table 1 suggest that ASA treatment either delayed or antagonised the development of sublethal retinoid toxicity. Although no differences were detected in the number of fractures after three weeks of drug delivery, the reduced mortality in the RA+ASA-treated mice strengthens the suggestion of benefit from ASA treatment. Agents other than ASA are more potent inhibitors of prostaglandin synthesis¹⁵; and if prostaglandins do play a part in retinoid intoxication, the protection indicated by these results can probably be improved with optimal treatment.

Although more direct support of our hypothesis is required, a question worthy of early consideration is how prostaglandins might fit into a mechanistic scheme for retinoid intoxication. Mallia *et al.*¹⁹ have concluded that retinol toxicity occurs in rats when the binding capacity of plasma retinol-binding protein is exceeded. Plasma concentrations of free retinol and retinyl esters then become elevated. These results have also been demonstrated in humans²⁰. Similarly, saturation of intracellular or extracellular proteins that bind retinoids would result in higher concentrations of free retinoids. Free retinol^{19,20} and free retinoids^{21,22} destabilise lysosomal membranes. The subsequent release of lysosomal enzymes, particularly phospholipase A, induces prostaglandin synthesis²³. Destabilisation of lysosomal membranes and release of lysosomal enzymes have been invoked to explain the local elevation of prostaglandin concentrations following

Table 1 Effects of retinoic acid alone and in combination with aspirin on Swiss mice

Day	Group	0	No. of fractures per survivor			No. of deaths per total
			1	2	3+	
8	RA	22/40	13/40	5/40	0/40	0/40
	RA + ASA	16/40	20/40	3/40	1/40	0/40
15	RA	7/36	10/36	8/36	11/36*	4/40
	RA + ASA	9/38	15/38	10/38	4/38*	2/40
22 (Day after last treatment)	RA	5/23	4/23	3/23	11/23	17/40†
	RA + ASA	5/37	7/37	13/37	12/37	3/40†

* The number of animals with three or more fractures is significantly lower in the RA + ASA group ($P < 0.05$).

† The number of deaths is significantly lower in the RA + ASA group ($P < 0.001$).

application of RA to guinea pig skin²⁴. Our observations suggest that systemic administration of RA has a similar effect. Rational control of retinoid intoxication will have an important influence on the development of retinoids for human use.

L-Dopa methyl ester as a new antitumour agent

L-DOPA (L-3,4-dihydroxyphenylalanine) is extensively used in man for the treatment of Parkinson's disease, and it can also inhibit selectively the growth of pigmented human melanoma cells *in vitro*¹. Demonstration of *in vivo* antitumour activity, however, has been lacking except in the special case of hormonally responsive mammary carcinoma² where the antitumour effect is thought to be mediated indirectly. Since *in vitro* cytotoxicity was not observed until concentrations of 600–1,200 $\mu\text{g ml}^{-1}$ were attained the use of the more soluble methyl ester derivative was proposed as a method for delivery of cytotoxic doses. *In vivo* antitumour activity of L-dopa methyl ester is reported here in the following tumour systems: L1210

lymphocytic leukaemia; P388 lymphocytic leukaemia and B-16 melanoma.

The results of *in vivo* antitumour experiments are summarised in Table 1. L-Dopa itself, because of insolubility, could not be administered to mice at doses greater than 100 mg kg^{-1} and did not show therapeutic activity at this dose. The methyl ester at the maximally tolerated dose of 600 mg kg^{-1} , however, exhibits activity in each of the test systems and is relatively

Table 1 *In vivo* antitumour activity of L-dopa methyl ester against L1210 and P388 murine leukaemias and B-16 melanoma

Drug	Dose (mg kg^{-1})	% Increase lifespan (ILS)*		
		L1210	P388	B-16
L-dopa methyl ester	500	+33	+46	+22

Ro4-4602 and L-dopa methyl ester	200+800			+25
	200+1,000	+44	+45	+30
	200+1,250	+55	+36	
MK 486 and L-dopa methyl ester	100+1,000	+55	+70	

L-Dopa and Ro4-4602 were gifts from the Hoffman LaRoche Company, Nutley, New Jersey; MK 486 was from the Merck, Sharpe and Dohme Co., West Point, Pennsylvania; L-dopa methyl ester was from the Sigma Chemical Company, St Louis, Missouri. Antitumour activity of each compound was determined by measuring the median ILS of mice given intraperitoneal (i.p.) inoculations of either 1×10^6 P388, 1×10^6 L1210 lymphocytic leukaemia cells or 0.5 ml of a 1:10 homogenate of B-16 melanoma tumour. The assay procedures followed the standard National Cancer Institute protocols³ for these tumour systems, with treatment beginning on the first day after tumour inoculation and continuing daily for 7 d with L1210 and P388 and 12 d for B-16 tumour. Agents were given i.p. in saline. Ro4-4602 was given 1 h before treatment with ester. C57Bl \times DBA/2 F_1 male mice (Jackson Laboratory, Bar Harbor, Maine) were used throughout. Percentage ILS was calculated according to the equation: % ILS = $100 \times (t/c - 1)$ where t is the median survival time (in d) of the treatment group and c is the median survival time of the control group.

*Values are significant at $P < 0.001$ unless otherwise noted.

†NS, Not significant.

‡Administered daily for 24 d.

active against the B-16 melanoma, which is considered to be highly refractory to conventional agents. The combination of L-dopa methyl ester with the inhibitors of dopa decarboxylase benserazide (Ro4-4602) and carbidopa (MK 486) (refs 3, 4) results in a marked increase in both the antitumour effect and the maximally tolerated dose.

Table 2 summarises the effects of L-dopa methyl ester on thymidine, uridine and leucine incorporation in the S-91 Cloudman melanoma and L929 mouse fibroblast *in vitro*. There is a selective and profound inhibition of DNA synthesis as measured

during drug exposure, with relatively greater inhibition in the melanoma cells. Uridine and leucine incorporation are largely unaffected. The greater inhibition observed in the pigmented line as well as the activity observed against B-16 melanoma may be related in part to the role of L-dopa as a biochemical intermediate in the formation of the pigment, melanin¹.

Although the precise cellular target of L-dopa methyl ester is not known, the pharmacological factors important to *in vivo* activity may be inferred. The acute toxic effects of L-dopa are mediated by its conversion to dopamine by the enzyme L-aromatic amino acid decarboxylase. At the high doses of L-dopa administered, a hypercatecholamine-type state was observed. The animals became agitated and tremulous and usually died with 1–2 h after administration. These acute toxic effects of L-dopa are probably mediated by its conversion to dopamine by the enzyme, L-aromatic amino acid decarboxylase (dopa decarboxylase). The striking increase in both the therapeutic

through inhibition of DNA synthesis. Extensive experience with both L-dopa and dopa decarboxylase inhibitors in human disease should permit rapid evaluation of their potential clinical significance.

I thank Dr E. Frei III and Dr T. B. Fitzpatrick for advice and encouragement.

	1,200	84 \pm 3	67 \pm 11	76 \pm 8

Values represent % inhibition and are mean \pm s.e.m. for triplicate determinations. The origin and maintenance of cell lines has been described in detail previously. Cells were grown in McCoy's 5A medium supplemented with 15% foetal calf serum, 100 units ml^{-1} of penicillin and 100 $\mu\text{g ml}^{-1}$ of streptomycin¹. Cells were plated in Linbro multi-well tissue culture trays and after 48 h they were in the log phase of growth. Medium was then aspirated, the monolayer washed and 1 ml of serum-free medium containing 2 $\mu\text{Ci ml}^{-1}$ of either ³H-thymidine (specific activity 2 Ci mmol^{-1}), ³H-5-uridine (specific activity 25 Ci mmol^{-1}), or ³H-leucine (specific activity 41 Ci mmol^{-1}) (New England Nuclear, Boston, Massachusetts) was added. After 60 min at 37 °C medium was removed, cells were washed once with saline and 1 ml of 10% trichloroacetic acid was added. The precipitate was washed three times with 0.9% sodium chloride and 0.5 ml of 1.0 M KOH added. Precipitate containing RNA, DNA and protein was then digested at 37 °C for 4 h and an aliquot added to scintillation vials containing Aquasol (New England Nuclear).

effect and maximally tolerated dose observed by pretreatment with inhibitors of this enzyme, may be related to the resulting elevated plasma levels of L-dopa and decreased levels of dopamine⁵. Alternatively, since Ro4-4602, an analogue of L-dopa, exhibited significant antitumour activity in L1210 and P388 systems, ($P < 0.001$), the increase in activity of this combination may be partially the result of an additive antitumour effect.

An intriguing possibility concerning the mechanism of action of L-dopa methyl ester and Ro4-4602 may be proposed. It is well known that L-dopa can combine with cysteine to yield 5-cysteinyl-dopa, a metabolite found in large amounts in the urine of patients with metastatic melanoma⁷. Livingston *et al.* have demonstrated⁸ that a large number of lymphoid and myeloid tumour lines, including L1210 and P388, are unable to grow in tissue culture in the absence of pre-formed L-cysteine⁸. It is possible, therefore, that L-dopa methyl ester and its analogue Ro4-4602 function as sulphhydryl scavengers, depriving tumours of essential growth factors.

L-Dopa methyl ester is a novel and potent antitumour agent in experimental tumour systems. It seems to act primarily

Dopamine agonists induce recovery from surgically-induced septal rage

ALTHOUGH recovery of function following brain damage has long been known to occur, the mechanisms involved are not completely understood¹. Of relevance to this problem are reports of pharmacological facilitation of recovery from brain damage in humans² and from experimentally-induced nervous system lesions in animals^{3–9}. We have previously reported that L-dopa injections produce a dramatic and apparently permanent abolition of the hyper-reactivity or rage syndrome that results from surgical damage to the septal nuclei of the rat forebrain¹⁰. Independent confirmation of this finding has also appeared¹¹. We report here that other dopamine agonists share this ability to attenuate or abolish the septal rage syndrome (SRS).

Individually housed male Long-Evans hooded rats (280–320 g) were anaesthetised with sodium thiopental and subjected to bilateral radio frequency lesions of the septal nuclei, using standard surgical and stereotaxic techniques. These lesions destroyed the medial and lateral septal nuclei and damaged the adjacent caudate nuclei, nucleus accumbens septi, and stria terminalis.

After recovery from the anaesthesia, approximately 60% of the lesioned animals exhibited a clear and persistent SRS, consisting of explosive reactivity to visual, tactual and auditory stimulation, coupled with pronounced biting, attack, fleeing, muscle tension and muricide¹². These hyper-irritable animals were then returned to their home cages; and, on the next day, rated for SRS hyperirritability¹³ in special observation chambers. Each animal was then given an intraperitoneal injection of one of the following: L-dopa (100, 60, 40, 30 or 10 mg per kg body weight), apomorphine (20, 15, 10 or 5 mg per kg), pibedil (300 or 200 mg per kg), amphetamine (4 or 2 mg per kg), methohexital (40 mg per kg), or saline. Each animal was returned to its home cage, and then placed in the observation chamber and rated for hyperirritability at 0.5, 1, 1.5, 2, 3, 4, 24, 48, 72, 96, and 120 h post-injection. All ratings of drug-injected animals were done blind. The methohexital treated animals were additionally rated at 0.25 and 0.75 h post-injection, and the apomorphine animals were also rated at 5 and 6 h. A few animals from some groups were also rated at times beyond 120 h (up to 1 month after injection). In this particular preparation, competing stereotypic behaviours were not observed for any of the doses of the catecholaminergic agonists used. Statistical analyses of changes in hyperirritability were performed as appropriate using the Friedman non-parametric analysis of variance (χ^2), the Wilcoxon matched-pairs signed-ranks test (T), and the Mann-Whitney rank test for independent samples (U).

Saline-injected animals (Fig. 1f) exhibited a constant level of irritability for the first 24 h, followed by gradual diminution over

Fig. 1 Post-injection changes in SRS brain lesion symptoms ('irritability') following single administrations of *a*, L-dopa: ●, 100 mg per kg body weight, $n = 8$; ○, 60 mg per kg, $n = 5$; ■, 40 mg per kg, $n = 3$; □, 30 mg per kg, $n = 4$; ▲, 10 mg per kg, $n = 4$. *b*, Apomorphine: ●, 20 mg per kg, $n = 12$; ○, 15 mg per kg, $n = 5$; ■, 10 mg per kg, $n = 6$; □, 5 mg per kg, $n = 5$. *c*, Piribedil: ●, 300 mg per kg, $n = 7$; ○, 200 mg per kg, $n = 3$. *d*, Amphetamine: ●, 4 mg per kg, $n = 10$; ○, 2 mg per kg, $n = 6$. *e*, Methohexital, 40 mg per kg, $n = 14$. *f*, Saline, $n = 10$.

the ensuing 5 d ($\chi^2 = 47.8$, $P < 0.001$), similar to non-injected animals. In contrast, animals given L-dopa (100 mg per kg) showed a dramatic and prompt return (Fig. 1*a*) to pre-operative levels of irritability (for the 0–4 h post-injection period, $\chi^2 = 43.8$, $P < 0.001$). Latency for a measurable effect was 90 min ($T = 0$, $P < 0.01$), and by 120 min after injection, the animals were indistinguishable from non-lesioned controls (the difference between the 100 mg per kg L-dopa animals and the saline controls also reaching significance by 120 min after injection; $U = 1.5$, $P < 0.001$). The L-dopa animals showed normal righting, placing and balance reflexes, and gave no appearance of being sedated; they continued to eat and drink, and remained normally responsive to environmental stimuli. The L-dopa abolition of lesion-induced SRS symptoms was also noteworthy for its permanence; none of the 100 mg per kg treated animals showed return of hyperaffective behaviour when examined up to 1 month post-injection. At 60 mg per kg L-dopa, a less marked, but still prompt and clear, attenuation of lesion-induced symptoms occurred ($\chi^2 = 19.8$, $P < 0.01$).

Animals given apomorphine also showed a drug-induced SRS amelioration (Fig. 1*b*). Apomorphine at 20 mg per kg produced complete and permanent abolition of lesion-induced symptoms within 120 min ($\chi^2 = 35.4$, $P < 0.001$); lower doses produced less effect on the time course of recovery (Fig. 1*b*). As with L-dopa, the animals were not merely sedated, and the drug-induced behavioural change was permanent.

Piribedil and DL-amphetamine produced differing effects on the time course of SRS recovery (Fig. 1*c, d*). Piribedil produced the same initial SRS amelioration during the first 4 h as L-dopa and apomorphine (χ^2 for 200 mg per kg piribedil = 15.1, $P < 0.01$; χ^2 for 300 mg per kg piribedil = 26.7, $P < 0.001$). But, this was followed by subsequent SRS increase at 24 and 48 h (most noticeable in the 300 mg per kg animals, which showed the most SRS attenuation during the first 4 h ($\chi^2 = 9.3$, $P < 0.05$)). The irritability of the piribedil-injected rats then attenuated over the next 4 d (χ^2 for 200 mg per kg = 8.5, $P < 0.01$; χ^2 for 300 mg per kg = 13.0, $P < 0.01$) at the same rate observed in untreated controls. Amphetamine produced an initial SRS increase during the first 90 min (only the 2 mg per kg animals being significant; $\chi^2 = 9.25$, $P < 0.01$), followed by a rapid and permanent SRS abolition (χ^2 for 2 mg per kg = 44.4, $P < 0.001$; χ^2 for 4 mg per kg = 43.6, $P < 0.001$).

In marked contrast to the L-dopa, apomorphine, piribedil or amphetamine effects, the short-acting barbiturate methohexital produced immediate sedation ($T = 0$, $P < 0.001$), followed by rapid return to full, lesion-induced SRS irritability ($\chi^2 = 29.1$, $P < 0.001$), which then attenuated over the next 5 d ($\chi^2 = 27.8$, $P < 0.001$) at a rate similar to control animals (Fig. 1*e*). Essentially, methohexital produced a brief and profound sedation, but no effect on the time course of recovery from the lesion. Thus, the action of L-dopa and apomorphine cannot be ascribed to the effect of handling during transient tranquillisation.

Apomorphine seems relatively selective in its dopamine receptor stimulating properties^{14,15}, so activation of dopamine receptors seems sufficient to induce neuronal processes leading to recovery from septal damage. The initial SRS exacerbation under amphetamine may reflect a noradrenergic effect (preliminary data from SRS animals given imipramine, which also seems to intensify the SRS symptoms, seem confirmatory); the biphasic response to piribedil may reflect an action on presynaptic release of dopamine at brain sites distinct from the sites wherein apomorphine and L-dopa exert their effects¹⁶.

Our data contrast with reports of pharmacological diminution of SRS symptoms by neuroleptic agents, barbiturates, physostigmine, chlorthalidoxepoxide and non-narcotic analgesics¹⁷⁻²⁰. In these cases, the effects were transient and most closely resemble the present methohexital effect (albeit with less brief and profound behavioural inhibition). There are also reports of sedative and/or excitatory effects of L-dopa and related compounds on normal or brain-damaged animals, but these effects, too, are transient and reversible. The only previous report of permanent SRS abolition is that of Dominguez and Longo⁹, using *p*-chlorophenylalanine (pCPA). These data have been interpreted to implicate a serotonergic role in SRS recovery⁹, but we suggest that they may support a catecholaminergic (possibly dopaminergic) role in SRS recovery, since the time course of the action of pCPA action on the SRS is more consistent with an action on catecholaminergic systems²¹⁻²³.

The time course that we find for dopamine agonist-induced SRS recovery is only a few hours. Most neurological or behavioural processes invoked as explanations for recovery from brain damage have time courses measured usually in weeks, for example neural reorganisation, vicarious function, denervation supersensitivity, axonal sprouting and regrowth, and behavioural substitution¹. Changes in blood-brain barrier permeability²⁴ and diaschitic alterations in brain function^{2,25} may have shorter time courses, however. We are unable to find any alteration in blood-brain barrier permeability to noradrenaline in septally lesioned animals displaying SRS symptoms (uptake of intravenous ³H-noradrenaline into brain tissue was studied in six SRS, six septally-lesioned non-irritable, and six sham-operated rats 24 h after surgery; no differences between groups were found). The possibility of a diaschitic process remains—dopaminergically induced SRS recovery may involve the return of function in transiently dysfunctional regions either adjacent to or neuronally connected to the lesioned area. Possible regions of transient dysfunction might include the fibres and nuclei of the dopamine-rich mesolimbic forebrain system^{26,27}, for example, the nucleus accumbens adjacent to the septal nuclei, and the olfactory tubercle and anterior amygdala, reciprocally connected to the septum²⁸. The mechanism by which dopaminergic stimulation might hasten recovery of function in these areas remains to be determined.

Viable chimaeras produced from normal and parthenogenetic mouse embryos

PARTHENOGENESIS occurs spontaneously in about 10% of ovulated eggs of inbred strain LT/Sv mice^{1,2} and is experimentally inducible in other strains by various physical and chemical agents (see ref. 3 for review). The development of most parthenotes seems normal up to the expanded blastocyst stage⁴. They implant in the uterus, but, for reasons unknown, are resorbed within a few days. Although they rarely survive to 8 d of gestation when they develop somites, heart muscle, amnion, and neuroepithelium, Kaufman *et al.*⁵ obtained two embryos with 25 somites by transferring parthenogenetic blastocysts to the uteri of ovariectomised females treated with exogenous hormones. Even though parthenogenetic embryos do not survive to birth, their cells contain genetic information that permits prolonged survival. If two-cell parthenotes are cultured to the blastocyst stage and then grafted to extrauterine sites such as the testis or kidney, they may survive as teratomas composed of several types of tissues and undifferentiated embryonal cells (refs 1, 6 and L.C.S. and D.S.V., unpublished). Furthermore, strain LT/Sv spontaneous ovarian teratomas contain numerous differentiated tissues composed of parthenogenetically derived cells. The questions remains—why do parthenotes not survive at the organismic level *in utero*? Eicher and Hoppe⁷ used experimental chimaeras composed of normal and abnormal embryos to transmit a recessive X-linked lethal mutation, and we considered the possibility that parthenogenetic embryonic cells might also be rescued if combined with normal embryonic cells. Here we present evidence of production of at least two viable chimaeras between normal and parthenogenetic embryos.

Parthenogenetic eight-cell embryos were obtained from F₁ hybrid females produced by mating females of the LT/Sv strain to males of the incipient recombinant inbred strain LTXBJ (L.C.S. and D.S.V., unpublished). (The progenitors of LTXBJ were strains LT/Sv and C57BL/6J. Strain LTXBJ had been inbred for 11 generations of brother × sister matings when the experiments were initiated.) Nearly all of the females of the LTXBJ recombinant strain have bilateral ovarian teratomas at 3 months of age. These teratomas are derived from parthenogenetically activated ovarian eggs. About 30% of their ovulated eggs undergo spontaneous parthenogenetic development. (LT/Sv × LTXBJ)F₁ hybrid females have the same high incidence of spontaneous parthenogenesis as LTXBJ females.

Inbred strain LT/Sv is homozygous for the alleles *a*, *B⁺*, *C*, and *Gpi-1^a* at the agouti, brown, albino, and glucose-phosphate-isomerase-1 loci, respectively. LTXBJ is homozygous for the

alleles *a*, *B*, *C*, and *Gpi-1^b*. Although parthenogenetic embryos from the LT/Sv strain are diploid (P. C. Hoppe, personal communication), it is not known whether they result from initiation of mitosis in primary oocytes or secondary oocytes (lack of the second meiotic division), or diploidisation of haploid ootids. Regardless of their origin the parthenogenetic embryos from the (LT/Sv × LTXBJ)_F₁ females would appear *a/a C/C*. Depending on the nature of their origin, however, their genotypes for the brown and glucose-phosphate-isomerase-1 loci could be homozygous (for either allele) or heterozygous. Interpreting the origin of parthenogenetic cells in chimaeras was further complicated because we combined two parthenogenetic embryos per single normal embryo to form each chimaera. The two parthenotes could have different genotypes.

The normal eight-cell embryos were derived from eggs of albino 129/Sv (homozygous *A^w*, *B*, *c*, *Gpi-1^a*) females fertilised by sperm from A/HeJ (homozygous *a*, *b*, *c*, *Gpi-1^a*) males. Thus, these *F*₁ embryos were genotypically *A^w/a*, *B/b*, *c/c*, *Gpi-1^a/Gpi-1^a*.

Experimental chimaeras were produced by aggregating eight-cell embryos *in vitro*⁸. After removal of the zona pellucida with Pronase, one normal and two parthenogenetic morulae were combined in Whitten's medium⁹ and cultured overnight. The aggregated 'triplets' were then introduced into the uteri of (SJL × C57BL/10)_F₁ pseudopregnant females. To date, 55 'triplet' embryos have been transferred into six pseudopregnant females and two litters have been delivered.

On 30 January 1977 a litter of five mice was delivered by a female that had received eight 'triple' embryos. Of the four live young, one was a male about half the size of his three female littermates. This male was white with small patches of pigmented hair on the back and head that could only have been derived from the parthenogenetic embryos. Some of the pigmented hair was agouti and some non-agouti indicating that the mouse was chimaeric with respect to hair follicle cells. Both irises had pigmented and non-pigmented areas (Fig. 1). No nipples were evident. At 26 d old the chimaeric male weighed 13 g, and his littermates weighed 16 g each.

Fig. 1 Eye of chimaera mouse. The non-pigmented areas were derived from a normally fertilised egg, the pigmented areas from one or two parthenogenetically activated eggs.

At 36 d old, blood samples were collected from the male and his four littermates and analysed for GPI (Fig. 2). All of the non-chimaeric females showed only the GPI-1A form of glucose phosphate isomerase. The red blood cells of the chimaeric male apparently included cells derived from the parthenogenetic embryos as shown by a GPI-1B band (Fig. 2) that could only

Fig. 2 Electrophoresis of red blood cell lysates on cellulose acetate gels stained for glucose phosphate isomerase using method of Eichler and Washburn¹⁰. In slots 1–3 and 8 are lysates from the four normal female sibs (GPI-1A) of the chimaeric male. Slot 5 includes lysate from a C57BL/6J male (GPI-1B) and slot 7 from a (C57BL/6J × DBA/2J)_F₁ male (GPI-1AB). Slot 4 (repeated in slot 6) contains lysate from the chimaeric male. Of interest are the two bands present in slots 4 and 6 that have migrated at a faster rate than the major band in the position of GPI-1A. These two minor bands line up such that one is in the same position as the GPI-1AB (hybrid) band and the other in the position of the GPI-1B band. It seemed that the slower of the two bands (position of GPI-1AB hybrid band) stained more intensely than the faster band (position of GPI-1B), as is the case in lysates from a *Gpi-1^a/Gpi-1^b* individual, suggesting that at least one parthenogenetically-derived embryo in the chimaeric male mouse was of the *Gpi-1^a/Gpi-1^b* genotype.

result if cells of parthenogenetic origin were present. In addition, a GPI-1AB band was evident. Its intensity seemed greater than the GPI-1B, as is the normal case of *Gpi-1^a/Gpi-1^b* cells, suggesting that at least one of the parthenogenetic embryos was of the *Gpi-1^a/Gpi-1^b* genotype. The presence of a GPI-1AB band would imply that at least one of the parthenogenetic embryos resulted from mitosis of a primary oocyte or lack of a second meiotic division in a secondary oocyte (with crossing over between the centromere and the *Gpi-1* locus), but not diploidisation of haploid ootids. It is also possible that a polar body nucleus fused with its egg nucleus.

At 38 d of age the male gonads were examined through an incision in the abdominal skin and musculature. Both seemed to be normal testes. The right testis was removed and prepared for histological examination. There was no histological evidence that cells of parthenogenetic origin were present in the testis. To date the chimaeric male has sired 27 albino offspring, none of which shows evidence of parthenogenetic cells.

On 27 March 1977, a second litter of three mice was delivered. This litter was obtained by transferring 9 'triple' embryos each composed of two LT/Sv parthenotes with one albino 129 embryo. The female of this litter was much smaller than its two male littermates. Both her irises were pigmented showing the presence of parthenogenetic cells.

The evidence presented here shows that cells of parthenogenetic origin can survive and participate in normal organ formation. Since both parents of the normal embryo were albino, all of the pigment cells in the coat and irises of both chimaeras must have been derived from parthenogenetic embryos. Since the agouti pattern is determined by the genotype of the hair follicle cells, the presence of agouti hairs in the male chimaera indicates that some of these cells originated from the parthenogenetic member. Finally, the presence in the male chimaera of LT/Sv strain-specific GPI shows that red blood cells were derived from parthenogenetic embryos of the chimaera.

Although our preliminary results indicate that parthenogenetic cells are capable of differentiating normally in combination with normal cells, it is still not clear why parthenotes cannot survive to term *in utero* in strain LT/Sv mice.

We thank W. K. Whitten and S. Carter for useful discussions

and for demonstrating the method of making chimaeras. We thank S. Reynolds and D. Dorr for technical assistance. This research was supported by grant CA 02662 from the USNIH, and GM 20919 from the National Institute of General Medical Sciences.

Note added in proof: It has recently been found that ovarian teratomas in mice are derived from oocytes that have completed the first meiotic division¹¹.

Ovarian teratomas in mice are derived from oocytes that have completed the first meiotic division

SPONTANEOUS ovarian teratomas are found in about 50% of strain LT/Sv mice by the time they are 90 d old¹. These teratomas result from parthenogenetic cleavage of ovarian oocytes. Some parthenotes reach a developmental stage equivalent to 7 d embryo before they become disorganised and further develop into a teratoma. Since some cleaved ovarian oocytes are accompanied by polar bodies, but others seem to lack them, it was uncertain whether the teratomas derive from oocytes that complete the first meiotic division or from oocytes that cleave mitotically without previous meiotic division.

A strain of mice having an even higher frequency of ovarian teratomas than LT/Sv was produced by making a recombinant inbred line from strains LT/Sv and C57BL/6J (L.C.S. and D.S. Varnum, unpublished). Nearly all of the females of this recombinant line, called LTXBJ, have bilateral ovarian teratomas by 90 d of age. Fortuitously, among the C57BL/6J genes retained in the recombinant strain is the *Gpi-1^b* allele at the glucosephosphate isomerase (*Gpi-1*) locus on chromosome 7. Since strain LT/Sv is homozygous for the *Gpi-1^a* allele at this locus, (LT/Sv × LTXBJ)_{F1} hybrids are heterozygous at *Gpi-1* and express the A, hybrid AB and B allozymes in a ratio of 1:2:1 (Fig. 1a).

Electrophoresis of 23 teratomas from _{F1} female mice revealed a homozygous A or B allozyme banding pattern in 21 cases (Fig. 1b). The other two teratomas showed the 1:2:1 heterozygous banding pattern, indicating that they were heterozygous *Gpi-1^a/Gpi-1^b*.

We concluded from these results that the teratomas found in the (LT/Sv × LTXBJ)_{F1} female mice originated from parthenogenetically cleaved oocytes which had completed the first meiotic division (Fig. 2). In 21 of 23 cases, this division segregated the *Gpi-1^a* and *Gpi-1^b* alleles so that the parthenogenetic embryo and subsequently the teratomas were homozygous for either of those alleles at the *Gpi-1* locus. In the other two cases, where the heterozygous banding pattern was found, the most probable conclusion is that crossing-over has occurred between the centromere and the *Gpi-1* locus, so that the *Gpi-1^a* and *Gpi-1^b* alleles

were located on two chromatids attached to the same centromere.

Other studies on the origin of ovarian teratomas in women who were heterozygous for alleles producing allozymes of glucose-6-phosphate dehydrogenase and phosphoglucomutase, have shown that these teratomas were homozygous for the alleles in most cases, and thus that they arose from oocytes that had completed the first division of meiosis².

Fig. 1 *a*, Electrophoresis of supernatants prepared from ovaries (slots 1–6, and 8) and spleen (slot 7) from (LT/Sv × LTXBJ)_{F1} mice. Male LTXBJ mice were mated with female LT/Sv to produce the hybrids. At 8–10 weeks of age, the _{F1} females were autopsied and teratomas were removed while taking care to contaminate the tumour with as little ovarian tissue as possible. Excessively bloody tumours were not used. Pieces of tissue were homogenised with ground glass microhomogenisers in 0.05 ml 50 mM Tris-HCl buffer, pH 7.5, containing 1 mM EDTA and 1 mM β-mercaptoethanol. The homogenate was centrifuged for 20 min at 16,000g and the supernatant solution used as the enzyme source. Electrophoresis was carried out on Titan-III Zip Zone cellulose acetate plates (Helena Laboratories, Beaumont, Texas) with 0.043 M Tris, 0.046 M glycine buffer, pH 8.6, for 1.75 h at 180 V. Glucose phosphate isomerase (EC 5.3.1.9.) was detected with a 1% agar overlay containing 50 mM Tris-HCl, pH 8.0, 2.5 mM MgCl₂, 2.5 mM fructose-6-phosphate, 1 mM NADP, 0.1 mg ml⁻¹ phenazine methosulphate, 0.5 mg ml⁻¹ nitroblue tetrazolium and 5 IU ml⁻¹ glucose-6-phosphate dehydrogenase. The GPI-1B form in slot 2 appears darker than the GPI-1A, suggesting that this piece of ovary was contaminated with some teratoma tissue which was not obvious when the sample was taken. A piece of _{F1} tissue was tested from each animal from which a teratoma was assayed to assure heterozygosity. *b*, Electrophoresis of supernatants prepared from teratomas from (LT/Sv × LTXBJ)_{F1} female mice. Samples 1–3 and 5–8 show either the GPI-1A or GPI-1B allozyme pattern. Sample 4 is one of the two teratomas that showed a hybrid allozyme pattern. Samples 7 and 8 were taken from contralateral ovaries of the same animal (slot 7, Fig. 1a) and are homozygous for alternative allozymes. In some teratomas, the hybrid AB allozyme and the other homozygous allelic product were detected, but in these cases the amount of the AB form greatly exceeded the minor homozygous form, indicating that the tumour was probably contaminated with normal ovarian tissue.

Preliminary chromosomal analysis of LT teratoma has indicated that most of the cells are diploid and a small number are polyploid (L.C.S. and D.S. Varnum, unpublished). Also, the parthenotes recovered from the oviduct of superovulated LT/Sv mice are also diploid, although at least one polar body was usually found (P. C. Hoppe, personal communication). Therefore, diploidisation of the egg karyotype must have occurred after the first division. The mechanism of this diploidisation is unknown but it is possible, in principle, that karyokinesis of the second

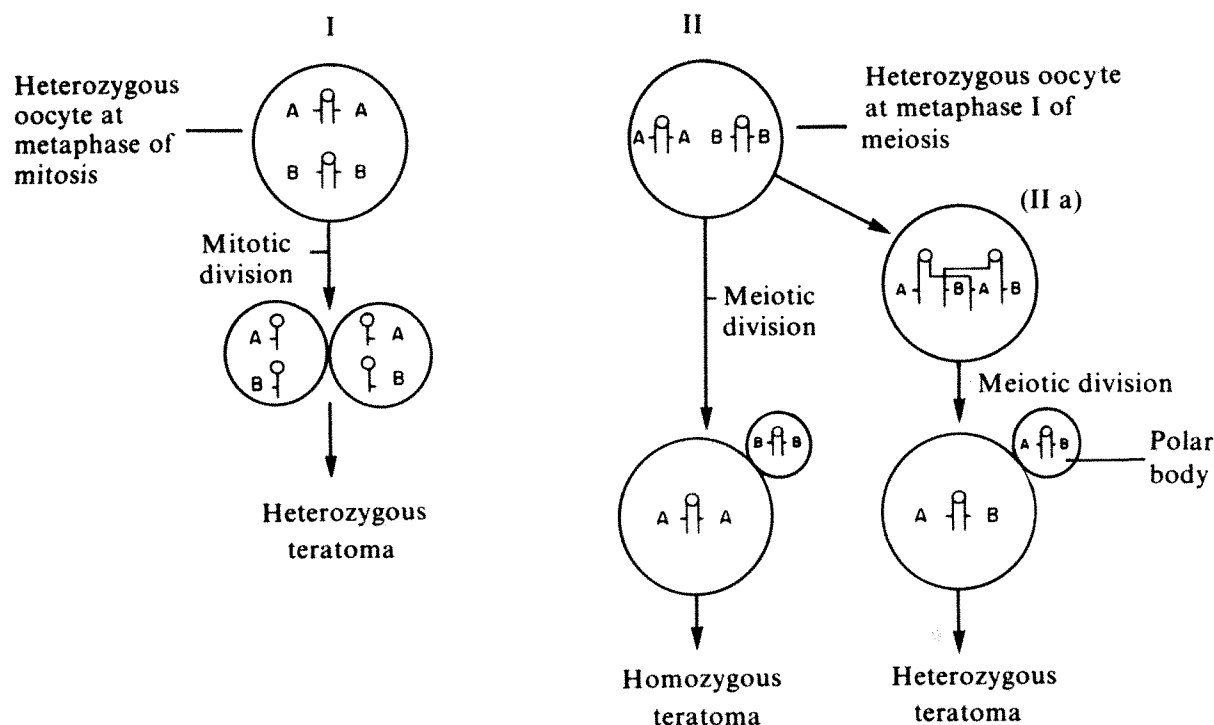

Fig. 2 Diagrammatic representation of alternatives for the distribution of alleles at the *Gpi-1* locus (A and B refer to the *Gpi-1^a* and *Gpi-1^b* alleles, respectively). The GPI enzyme consists of two subunits which associate randomly. Consequently, homozygous *Gpi-1^a* or *Gpi-1^b* cells contain enzyme with two A or B subunits, respectively. Heterozygous *Gpi-1^{ab}* cells contain three forms of the enzyme: one with two A subunits, one with an A and a B subunit, and one with two B subunits in a 1 : 2 : 1 ratio. If teratomas originate from oocytes which cleave mitotically without previous meiotic division (alternative I), then all teratomas would show the heterozygous banding pattern for GPI. If, however, the first meiotic division occurs before parthenogenetic cleavage, then (as the data presented here indicates) most teratomas would be homozygous for either the GPI-1A or GPI-1B allozymes (alternative II). In a minority of cases, heterozygous teratomas would be found resulting from a chromatid exchange between the *Gpi-1* locus and the centromere (IIA).

meiotic division occurs without cytokinesis, thus suppressing the formation of polar body II; or that there is a fusion of the second polar body with the ovum. Our preliminary results do not allow us to distinguish between these possible alternatives.

Extreme sensitivity of some intestinal crypt cells to X and γ irradiation

THE destructive effects of radiation have been studied for 80 yr. Most techniques involve looking at the surviving cells, which tend to be the more resistant cells of the tissue. On the assumption that the results are representative of all cells in the tissue, many conclusions have been drawn. On the other hand, Cheng and Leblond have used tritiated thymidine ($^3\text{HTdR}$) to kill cells synthesising DNA in the crypts of the small intestine¹. Two surprising features of their experiments have provoked little comment. First, very low doses (40-50 μCi per mouse) of $^3\text{HTdR}$

caused measurable cell killing and second, the killing (evident from the presence of labelled apoptotic-like² phagosomes¹) was not random throughout the crypt but occurred selectively at the crypt base where relatively few cells are in S (refs 3 and 4) and where the stem cells are presumably located^{1,3-5}. I report here that the presence of hypersensitive cells at the base of the crypts can be demonstrated after whole-body X or γ irradiation, and to describe the time sequence for the production and loss of these killed cells together with their dose-response relationship.

Figure 1 compares the changes in the number of apoptotic cells in sections of the whole crypt and in sections of the lower third of the crypt after whole-body irradiation. Peak values are obtained within 3-6 h, with 2-3 of the total apoptotic bodies occurring in the lower third. Because the upper third contains few apoptotic bodies after 3 or 6 h this represents a twofold difference in the yield in the base and mid-crypt region. The difference in sensitivity may be much greater for certain cell positions because the base region contains the mature Paneth cells which do not contribute extensively to the apoptotic yield. The control level of apoptoses fluctuates slightly with the time of day but is not affected by handling of the animals (saline injections) or sham irradiation (Fig. 1).

Apoptotic bodies in the crypt base can be ingested and gradually absorbed by neighbouring Paneth cells, stem cells or amplifying committed cells^{1,3-5}. In the last case they will be carried rapidly into the mid-crypt region and then out of the crypt on to the villus. For higher doses the apoptotic yield may remain at elevated levels for longer times because cell cycle progression, crypt transit and cell movement may be retarded when many cells are killed; furthermore, other more radiation-resistant cells may take longer to appear apoptotic. In the case of ingestion by Paneth or stem cells, the apoptotic bodies will remain in the basal region for a longer time, either until absorbed to a residual body no longer detectable in the light microscope (Paneth cells) or until passed by stem cell division into the cytoplasm of a new committed cell

(because stem cells cycle more slowly than the committed cells^{1,3-7}). For these reasons sampling was restricted to either 3 or 6 h after irradiation and in many cases the average of both 3 and 6-h samples was used.

Figure 2 shows the dose dependence for the yield of apoptotic cells in the lower third of the crypt 3 h after irradiation. There was a fivefold increase in yield after 1–2 rad and a tenfold increase after 5 rad. Beyond 20 rad the yield increased more slowly. Because the points are somewhat scattered it is not clear whether the yield was constant beyond 20 rad or continued to increase gradually. The highest values were obtained after a dose of 900 rad and represent a 30–40-fold increase. Beyond 900 rad, crypt survival seems to be related exponentially to dose⁸⁻¹⁰, with a D_0 value of 100–200 rad⁸⁻¹⁰. Thus a few cells (perhaps one to three) survived with an intact reproductive potential after 900 rad, that is 98–99% of the 250 crypt cells were sterilised. But only a very small fraction of these sterilised cells appeared apoptotic.

Figure 3 shows the same data in greater detail with the crypt base and total crypt apoptotic yields using the average of both the 3- and 6-h samples. The points show less scatter and illustrate that

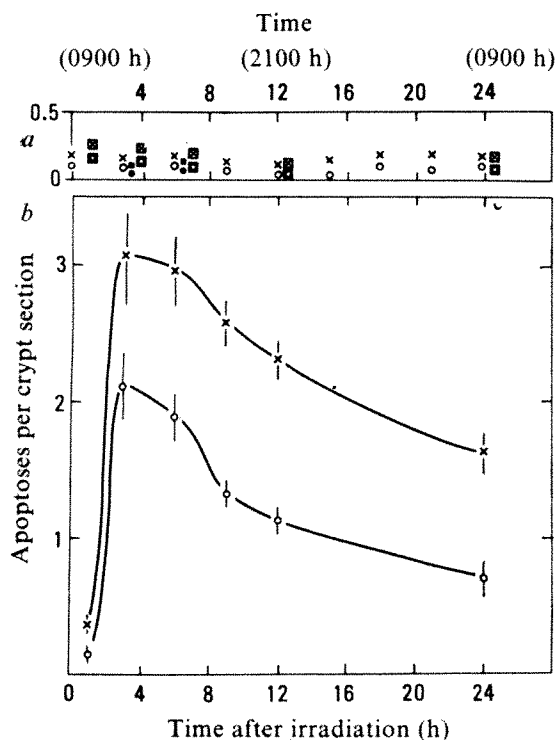

Fig. 1 Apoptotic yield in unirradiated mice (a) and after 63 rad whole-body ¹³⁷Cs γ irradiation (520 rad min⁻¹)(b). Each point shows the mean and standard error of at least four individual mouse values. Scoring was done at $\times 500$ magnification on haematoxylin and eosin 5–7- μ m paraffin sections. Forty crypt sections were scored from each mouse. Crypts were scored only if they were well sectioned longitudinally with the Paneth region, a clear lumen and at least 17 cells up one side of the crypt (the mean number of cells up one side was about 22). The crypts were then divided into three regions, each of approximately 1/3 the total number of cells. It is assumed that the number of apoptotic cells was directly proportional to the number of cells killed over the range of radiation doses studied. Because apoptotic cells tend to be centripetally positioned and disperse slightly a good longitudinal crypt section yields about 60% of the apoptoses per crypt (as revealed by comparing sections and whole squashed crypts). Thus the total number of hypersensitive cells per crypt would have been about 4.5 (based on the value at 40 rad). Groups of untreated animals were killed at various times of the day (\times , total; \circ , base), at various times after an intraperitoneal injection of physiological saline (0.2 ml) (cross in square, total; circle in square, base), and 3 and 6 h after sham irradiation (\blacksquare , total; \bullet , base). In none of these cases did the total apoptotic yield exceed 0.25 per crypt section (overall mean 0.17 total and 0.08 crypt base). There was thus an approximately 20-fold increase in total apoptoses within 3 h of irradiation. The proportion of apoptotic cells is even larger when the crypt base is considered.

Fig. 2 Dose-response for apoptotic cells in the lower third of the crypt 3 h after irradiation. Apoptotic yield is plotted on a logarithmic scale against dose on a linear scale. Each point shows the mean, with its standard error, of at least four mice. \circ , Values for ¹³⁷Cs γ rays (520 rad min⁻¹); \times , 290 or 300 kVp X rays (30 rad min⁻¹). The errors on the doses were estimated to be about $\pm 5\%$ for all doses except the lowest γ -ray doses where it was not more than $\pm 20\%$.

radiation hypersensitivity was confined largely to cells in the base of the crypt. These results clearly illustrate the presence of some extremely sensitive cells in the lowest region of the crypt—in the region immediately above the Paneth cells and below most of the rapidly proliferating cells, that is, within the presumptive stem cell region^{1,5-7}. The number of hypersensitive cells per control crypt section is uncertain. If it is assumed that most of the hypersensitive cells are killed by 40 rad, which is just on the resistant portion of the dose-response curve shown in Fig. 3, the number of apoptoses observed after 40 rad would be close to the total number of hypersensitive cells present in a crypt section. The data (from Fig. 3) can thus be expressed as survivors rather than killed cells and a survival curve can be generated (Fig. 4). The resulting points are scattered about a line with a 50% effective dose of 8 rad and a D_0 of about 10 rad. This places these crypt cells among the most sensitive mammalian cells. Figure 4 shows that the most sensitive type of oocytes (stage 1) have a similar sensitivity¹² while the most sensitive spermatogonia (preleptotene)¹³ and the sensitive cortical thymic lymphocytes¹⁴ are more resistant than the crypt cells. An extreme sensitivity can also be seen in some early mouse embryo cells after doses in range 5–25 R (refs 15–17). This survival curve is speculative and the actual slope (D_0) depends somewhat on the value used for the number of hypersensitive cells per crypt, but whatever way the data are expressed, within the stem cell region at the crypt base there are clearly a few extremely radiosensitive cells. Preliminary observations indicate the presence of similar hypersensitive cells in the growing hair follicle matrix and colonic crypts.

The precise function of the radiosensitive cells in the crypt is uncertain. They do not represent any known histologically distinctive cell type (at the level of either light or electron microscopy). Their presence suggests at least two radiobiologically distinct crypt cell populations. If they are stem cells they must represent a subpopulation of the total complement of potential

stem cells (about 80 per crypt⁹) because the crypts are not destroyed when these hypersensitive cells are killed. The number of functional stem cells per crypt is uncertain but is probably about 20, that is about six times the number of hypersensitive cells. The subpopulation of hypersensitive cells might be at some extremely sensitive stage of the cell cycle peculiar to stem cells. The normal sensitivity changes through the cell cycle are relatively small and the sensitive phases (G_2 and M)¹⁸ do not exhibit sensitivities such as those shown here. It is not clear whether these apoptotic bodies are formed from interphase cells or from abortive divisions. In the latter case their appearance within 3h could suggest a hypersensitive point somewhere in G_2 .

One rad of radiation of this quality produces sufficient ionising tracks for at least one track to cross some part of about 50% of the cell nuclei (assuming an average diameter of about $4\mu\text{m}$). The average track length per rad per cell nucleus is about $2\mu\text{m}$. The average energy deposition per nucleus is 2KeV rad^{-1} . The data in Fig. 3 suggest that after 1 rad one sensitive cell in ten will have at least one track traversing its critical volume which might be about $1.4\mu\text{m}$ in diameter (that is about $1/20$ of the nuclear volume) and that one track crossing this volume is sufficient to kill that cell.

The mechanism by which these sensitive cells are killed is unknown, but DNA damage can be detected at similar doses (up to 5 rad)¹⁹. It has been suggested that stem cells would benefit from a mechanism by which newly synthesised DNA strands (containing replication errors) were selectively distributed to the committed cells and thus eliminated, ensuring the genetic stability of the stem cell DNA²⁰. In these conditions damage to the stem cell template DNA might be intolerable and the cells might die. The extreme sensitivity seen here would suggest that any DNA damage would result in death; furthermore that other cells differing in the way they normally handle their DNA may assume the role of regenerative stem cells which would be a potentially hazardous process because possibly imperfect DNA would be 'immortalised'. This assumes that the vital stem cells lack any means of repairing genetic errors. An alternative explanation implies the

Fig. 3 Dose-response for apoptotic cells in the lower third (base, \times and \circ) and the total crypt (\bullet). The individual data points are the mean of 3- and 6-h post-irradiation groups for X rays (\times) and γ rays (\circ). The insert shows the first nine data points for the base (0-12 rad).

Fig. 4 Survival curve for apoptotic sensitive crypt cells (\times , X rays, \circ , γ rays). Surviving fraction is plotted on a logarithmic scale against radiation dose on a linear scale. The points were obtained by assuming that there was an average of 2.7 apoptotic sensitive cells per crypt section (value reached at 40 rad, see Fig. 3). Data points for stage I oocytes¹² (\bullet), preleptotene spermatogonia¹³ (Δ), type B spermatogonia (\blacktriangle) and cortical thymic lymphocytes¹⁴ (\square) have also been plotted. The line has been fitted by eye and has a D_{01} of approximately 10 rad.

reverse, that the stem cells possess an extremely efficient means of restoring the DNA integrity; the stem cells may possess a mechanism for detecting template errors and (1) transferring G_1 induced errors by means of sister chromatid exchanges and mitosis to the committed daughter which subsequently dies, or (2) eliminating G_2 -induced errors by elevating the newer strands to stem cell template status and discarding the damaged DNA to a cell that subsequently dies. Any of these possibilities could explain the apparent indifference of the crypt as a whole to this type of death.

The significance of this phenomenon in public health (maximum permissible doses)—doses within the range studied here are delivered in several diagnostic radiological procedures—and radiotherapy, depends on the function of the hypersensitive cells and the mechanism by which they are killed.

This work was supported by grants from the MRC and the Cancer Research Campaign. I thank Jeffrey Searle for suggesting apoptosis; John Cairns and Don Major for helpful discussions; Irene Wylie for technical assistance and Caroline West for microscopy.

Cellular serine proteinase induces chemotaxis by complement activation

INFILTRATION of inflamed or injured tissues by polymorphonuclear leukocytes is a fundamental pathophysiological response. Undoubtedly, there are numerous mechanisms by which leukocytes are attracted to an area of damage. One possibility is that cellular injury could release or activate a proteolytic enzyme which could generate chemotactic factors. Extracts of parenchymatous tissues¹ and cells² are chemotactic when they are incubated with complement sufficient serum. Macrophages³ and leukocytes⁴ contain a proteinase which generates chemotactic peptides, and recently human polymorphonuclear leukocytes have been shown to secrete an enzyme which activates complement⁵. Lazarus and Barrett extracted and characterised a serine proteinase which induced polymorphonuclear leukocyte infiltration of the skin when injected intradermally⁶. Subsequently, this proteinase, which is both cytotoxic and phlogistic, has been purified to homogeneity from whole human skin⁷, human epidermis⁸, human lymphocytes⁹ and cultures of newborn mouse epithelium (G.S.L., unpublished). This report demonstrates that this proteinase is significantly more active than trypsin, plasmin or Pronase in generating polymorphonuclear leukocyte accumulation and that chemotactic activity is largely dependent on complement activation.

The procedure for purification of the enzyme has been described previously⁷; this was used with several modifications. Frozen human skin, obtained from amputated limbs, was minced and added to 10 volumes 50 mM phosphate buffer, pH 7.4, containing 1.0 M potassium chloride. The mixture was frozen and thawed five times and further extracted by agitation at 4 °C for 18 h. After centrifugation at 50,000g, the supernatant was subjected to 85% saturation with ammonium sulphate and the proteinase was extracted from the precipitate with a minimum volume of extraction buffer. The extract was concentrated and placed on a Sephadex G-75 superfine column and the eluted fractions containing the smallest molecular weight proteinase (molecular weight approximately 28,000) were combined and further purified by chromatography on a soybean trypsin inhibitor-Sepharose affinity column.

This purification method yielded a single protein band on polyacrylamide gel electrophoresis and SDS-polyacrylamide gel electrophoresis. Injection of the 250-fold purified enzyme into rabbits produced an antibody which gives a single line of identity in Ouchterlony double-diffusion plates against purified enzyme

and crude starting material. The enzyme was inhibited by diisopropyl fluorophosphate (DFP), soybean trypsin inhibitor, α_2 -macroglobulin and α_1 -antitrypsin. Further characterisation has demonstrated that it was not elastase, cathepsin G or plasminogen activator.

Polymorphonuclear leukocyte chemotaxis was assayed by the method of Snyderman *et al.*¹⁰. Sample (2 ml) was injected into the peritoneal cavity of a group of normal or C5-deficient male mice (Jackson Laboratories, Bar Harbor, Maine). After 12 h, the animals were killed by inhalation of carbon dioxide, and the peritoneal cavity was vigorously washed with 9 ml Dulbecco's Modified Eagle's Media with 10% foetal calf serum (GIBCO), containing 90 IU herapin (Upjohn). The peritoneal wash was counted for total number of white cells and for percentage polymorphonuclear leukocytes (PMN) by standard techniques. Results were expressed as absolute number of PMN. All assays were carried out in triplicate on three occasions, and the materials tested included saline controls, proteose peptone, a complement-independent chemotactic agent (9%, DIFCO Laboratories), and proteinase with and without inhibitors. Proteolytic activity of all materials was assayed by measuring production of trichloroacetic acid-soluble peptides from tritium-labelled casein⁸.

Polymorphonuclear leukocyte accumulation was directly proportional to enzyme concentration in the range 1-50 μ g enzyme protein. Table 1 compares the ability of the purified human proteinase to elicit polymorphonuclear leukocyte accumulation with other common proteolytic enzymes operative at neutral pH. Our enzyme (20 μ g) induced a brisk accumulation of polymorphonuclear leukocytes. Pre-incubation of enzyme with diisopropyl fluorophosphate (1 mM final concentration, 1 h, 25 °C) followed by exhaustive dialysis against physiological saline, almost completely inhibited polymorphonuclear leukocyte accumulation. These data suggest that enzymatic activity is necessary for polymorphonuclear leukocyte accumulation. By contrast, injection of 200 μ g plasmin, Pronase or trypsin attracted one-third the number of polymorphonuclear leukocytes into the peritoneum. This was not simply a function of increased proteolysis by our enzyme; expression of polymorphonuclear accumulation per amount of casein-degrading activity, revealed that our purified skin proteinase was 3-5 logs more effective in attracting polymorphonuclear leukocytes on a proteolytic activity basis than the other proteinases tested.

We next attempted to elucidate the mechanism by which our purified human proteinase induced such a significant polymorphonuclear leukocyte accumulation. Equal amounts of the purified proteinase were injected into normal and C5-deficient mice (Fig. 1). The enzyme evoked the expected dramatic response in normal mice, which was almost completely inhibited by DFP. By contrast, the enzyme was a quarter as effective in evoking polymorphonuclear leukocyte infiltration in C5-deficient mice. Furthermore, the minimal chemotactic response in C5-deficient mice could be reduced to control levels by pre-incubation of the enzyme with DFP. These data show that the enzyme evokes its chemotactic response principally through the complement cascade and probably requires the production of C5 fragmentation for maximal activity. The data also suggest that the proteinase is capable of inducing limited chemotaxis by a C5-independent mechanism.

Table 1 Relative chemotactic activity of proteolytic enzymes

	μ g Injected	Proteolytic activity (c.p.m. TCA-soluble protein)	PMN per mouse $\times 10^{-4}$	Chemotactic index PMN/c.p.m. proteolytic activity
Human skin proteinase	20	1.2×10^3	370	3,060
Plasmin	200	3.5×10^6	90	2.6
Pronase	200	2.8×10^7	126	0.05
Trypsin	200	6.2×10^7	128	0.02

Proteinases were assayed for proteolytic activity before injection and polymorphonuclear leukocyte (PMN) accumulation was measured 12 h after injection. Chemotactic index expresses PMN accumulation per unit of proteolytic activity.

Fig. 1 Purified human proteins (20 μg) and a comparable amount of enzyme inhibited with DFP, were injected into normal (a) and C5-deficient mice (b). Polymorphonuclear (PMN) leukocyte accumulation was determined 12 h after injection.

Our data suggest that cells contain a proteinase operative at neutral pH which is extraordinarily effective in activating complement and inducing polymorphonuclear leukocyte accumulation. The presence of this enzyme in whole skin⁷, human epidermis⁸, human lymphocytes⁹ and mouse epithelial cells in culture (G.S.L., unpublished), could suggest that cellular injury might activate this proteinase, which through the mediation of complement induces polymorphonuclear leukocyte accumulation. Such a mechanism might explain how cellular injury induces polymorphonuclear leukocyte accumulation.

The ECF-A tetrapeptides and histamine selectively enhance human eosinophil complement receptors

VARIOUS products of the anaphylactic reaction such as the ECF-A tetrapeptides¹ (Val-Gly-Ser-Glu and Ala-Gly-Ser-Glu)² and histamine^{3,4} preferentially attract the human eosinophil in chemotaxis *in vitro*. We have designed experiments to show whether these chemical mediators have a direct effect on the eosinophil cell membrane, as assessed by their capacity to alter receptors for either IgG or complement (C). We have established here that these two ECF-A peptides and histamine both enhance markedly the expression of eosinophil receptors for C3 but not for IgG. Neutrophil and monocyte receptors seemed to be unaltered and a number of other chemical mediators of hypersensitivity had no effect on these membrane markers when tested at comparable concentrations. Our demonstration of eosinophil membrane receptor enhancement by chemotactic factors may have more general biological significance in terms of how surface recognition mechanisms by phagocytic cells are regulated.

Receptors were measured by the 'rosette technique' using sheep red blood cells (RBC) sensitised with either IgG or C3b (Fig. 1). Human eosinophils, neutrophils⁵ and monocytes⁶ were prepared from venous blood from patients with eosinophilia of various aetiology and adjusted to a concentration of $4 \times 10^6 \text{ ml}^{-1}$ in

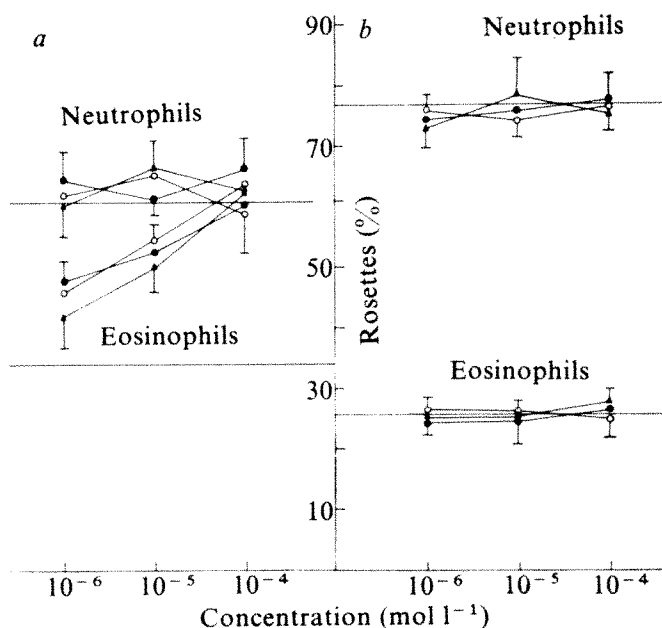

Fig. 1 The effect of increasing concentrations of the valyl- (●) and alanyl- (○) ECF-A peptides and histamine (▲) on a, EAC3b and b, EAG rosettes by human eosinophils and neutrophils. The lines represent the percentage rosettes of untreated eosinophils and neutrophils. Each point represents the mean of five experiments \pm 1 s.d. Dextrose-gelatin-veronal buffer (DGVB²⁺ pH 7.4) was used for washing sheep RBC during sensitisation and coating with various complement components. This was prepared by mixing equal volumes of isotonic veronal-buffered saline (containing 0.0015 M Ca²⁺, 0.0005 M Mg²⁺ and 0.1% gelatin-veronal buffer (GVB²⁺) with 5% dextrose in water containing the same concentration of Ca²⁺ and Mg²⁺ (ref. 10). The IgG and IgM fractions of rabbit antisera to sheep red cells were prepared by Sephadex G-200 gel filtration. Sheep cells were sensitised with either the IgG fraction for preparing EAG_{rab} (EAG) or IgM (EA_M^{rab}) for EAC1423b rosettes. Functionally pure human complement components were added sequentially to EA_M^{rab} to prepare C3b-coated cells as described¹¹. The amounts were as follows: 400 effective molecules of C1, 400 of C4, 50 of C2 and 2,500 of C3. This amount of C4 was insufficient to give EAC14 rosettes with neutrophils, eosinophils or monocytes¹¹. The valyl- ((HCl)-Val-Gly-Ser-Glu, molecular weight 427) and alanylpeptides ((HCl)-Ala-Gly-Ser-Glu, molecular weight 497) were a gift from Dr R. Camble (ICI Limited, Pharmaceuticals Division, Alderley Park, Macclesfield); histamine acid phosphate (BDH Chemicals Limited, Poole).

medium 199 (pH 7.4). Equal volumes of leukocyte suspensions and various concentrations of the pharmacological agents under study, or control medium alone, were mixed and incubated in a shaking water-bath at 37 °C for varying intervals. The cells were then washed twice in medium 199 and the numbers adjusted to $2 \times 10^6 \text{ ml}^{-1}$ in the same medium. An aliquot (0.1 ml) of IgG-(EAG) or complement-coated (EAC3b) red cells containing $1 \times 10^8 \text{ ml}^{-1}$ was then added to 0.1 ml of the cell suspension. The mixtures were centrifuged at 100g for 10 min at 4 °C and the pellets incubated at 0 °C (for EAG rosettes) or 37 °C (for EAC3b rosettes) for 30 min as described. The pellets were gently resuspended and smears were prepared in duplicate. The slides were dried in air, fixed in methanol and stained. Cells with three or more adherent erythrocytes were counted as rosettes. Two hundred cells were counted on each slide and the number of rosettes expressed as a percentage of the total number counted.

With no treatment the percentages of neutrophil, IgG or complement receptors were usually more than twice that of the eosinophil (Fig. 1). With increasing concentrations of the valyl- or alanyl-peptide, or histamine there was a dose-dependent enhancement of the numbers of eosinophils, but not of neutrophils, which formed rosettes with EAC3b. There was no increase in the numbers of eosinophils or neutrophils forming rosettes with EAG. When other pharmacological mediators, which included bradykinin and the prostaglandins PGE_1 , E_2 and $\text{F}_{2\alpha}$, were incubated at comparable concentrations (10^{-4} – $10^{-6} \text{ mol l}^{-1}$) to that of the ECF-A peptides or histamine, there was no appreciable increase in the numbers of eosinophil- or neutrophil-EAC3b rosettes (Table 1). An increase of 25% was observed with 5-hydroxytryptamine, but only at the highest concentration ($10^{-4} \text{ mol l}^{-1}$). The enhancement with the ECF-A peptides or histamine, with this dose was almost three times this value, thus achieving virtually the same percentage of rosetting eosinophils as neutrophils (Figs 1 and 2). The monocyte was also tested with the valyl- and alanyl-peptide and histamine but, unlike the eosinophil, there was no apparent alteration in the numbers of rosetting cells (Table 1). The enhancement of EAC3b eosinophil rosettes by the ECF-A peptides or histamine also increased with incubation time (Fig. 2). With the peptides, however, most of the increase in rosette formation was apparent at 40 min. In contrast, most of the histamine-induced rosette enhancement took place between 40 and 80 min.

These experiments suggest that the ECF-A peptides and histamine not only attract eosinophils selectively in chemotaxis but also have a direct effect on the eosinophil membrane as shown by the apparent increase in the numbers of complement receptors. It is not known whether this enhancement is caused by the generation of new receptors or whether receptors, previously 'hidden', are revealed as a result of membrane changes. The inability of these pharmacological agents to increase neutrophil and monocyte complement receptors emphasises further the unique, intimate relationship between the human eosinophil and

Fig. 2 The effect of time on enhancement of EAC3b rosettes by eosinophils and neutrophils following incubation with the valyl-(●) and alanyl-(○) ECF-A peptides and histamine (▲). Each mediator was tested at a concentration of $10^{-4} \text{ mol l}^{-1}$. The lines represent the percentage rosettes of untreated eosinophils and neutrophils. Each point represents the mean of five experiments $\pm 1 \text{ s.d.}$

these anaphylaxis-associated agents. We also explored the possibility that neutrophil and monocyte complement receptor enhancement may be revealed when the amount of C3 on the indicator cell was limited. In experiments in which the quantity of C3 used was adjusted to give approximately half the number of rosetting cells (that is, 1,000 effective molecules) however, there was no apparent increase in rosette formation following incubation with these agents. Similar negative results were found with neutrophils and monocytes when the amounts of IgG were decreased to give lower numbers of EAG rosettes. The reason why complement, and not IgG, receptors were altered by the ECF-A peptides and histamine is unknown. It was previously shown that IgG and C3b receptors act together to aid macrophage phagocytosis⁷. A similar mechanism may exist for eosinophils; optimal receptor ratio being determined by the presence of pharmacological mediators such as ECF-A and histamine.

The role of the eosinophil in immediate-type hypersensitivity is thought to be that of a homeostatic cell affecting mediator release,

Prostaglandins E_1 , E_2 and $\text{F}_{2\alpha}$ were supplied by Dr John Pike, Upjohn Company, Kalamazoo, USA; bradykinin triacetate and 5-hydroxytryptamine were obtained from Sigma, Kingston-upon-Thames, UK.

mediator inactivation and mediator replenishment by mast cells⁸. Their function in helminth disease may be that of a cytotoxic cell requiring the participation of IgG, in an analogous fashion to lymphocyte-antibody-dependent cell-mediated cytotoxicity⁹. Although complement does not seem to be required in this system, it is nevertheless possible that adherence by way of the C3 receptor may amplify the parasitocidal properties of eosinophils. Our observations may therefore, be of relevance in helminth disease where the IgE-mediated release of chemical mediators is well recognised. In any event, our finding of a new biological activity for both the ECF-A peptides and histamine may provide further insight into both the essential biochemical differences between human eosinophils and other blood leukocytes, and the way in which chemical mediators modulate recognition mechanisms by cell membranes.

Molecular basis for acquired haemoglobin H disease

HAEMOGLOBIN H (Hb H; β_4) disease results from a reduced rate of synthesis of the α chains of human adult haemoglobin (Hb A; $\alpha_2\beta_2$). In the absence of sufficient α chains, excess β chains form β_4 tetramers which are unstable, precipitate and cause a shortened red cell survival¹. Hb H disease is one of the α -thalassaemia syndromes. These disorders usually result from interactions of three α -thalassaemia (α thal) genes; α thal 1, α thal 2 and Hb Constant Spring. In many human populations the α -chain loci are duplicated, that is, there are two per haploid genome². The gene α thal 1 results from a deletion of both of the pair of haploid α -chain genes^{3,4}, α thal 2 from a deletion of one of the pair⁵, and Hb Constant Spring from a chain termination mutation affecting one of the linked loci which markedly reduces the output of α chains and produces a phenotype almost identical to α thal 2 (ref. 6). Haemoglobin H disease results from the inheritance of α thal 1 together with either α thal 2 or Hb Constant Spring. There have been occasional reports of an acquired form of Hb H disease occurring in association with leukaemia or related myeloproliferative disorders⁷⁻¹². We have studied the blood and bone marrow of a patient with acquired Hb H disease and we report here that it has a completely different molecular basis from the genetic form.

The patient (WD), an 81-yr-old British male, had a bizarre myeloproliferative disease which terminated in acute myeloblastic leukaemia. Full haematological and biochemical data will be presented elsewhere. His blood picture showed two cell populations; most of the cells were poorly haemoglobinised but about 5% seemed normal. Chromosomal analysis of the

Fig. 1 Hybridisation of human globin cDNA α and cDNA β to mRNA from the peripheral blood of WD. cDNA α and cDNA β were prepared by the hybridisation of 7 μ g of $\beta^0/\delta^0\beta^0$ -thalassaemia mRNA to 190 ng of 3 H-cDNA $\alpha\beta$ (prepared as previously described¹⁹ by RNA-dependent DNA polymerase purified from avian myeloblastosis virus, a gift from Dr Beard, Life Sciences Research Laboratories) in 50 μ l of hybridisation buffer (0.5 M NaCl, 25 mM HEPES, 10 mM EDTA pH 6.8, 50% formamide and 500 μ g ml⁻¹ of *Escherichia coli* RNA) for 3 h at 43 °C. The non-hybridised component (cDNA β enriched) was separated from the hybridised component (cDNA α enriched) by hydroxylapatite fractionation at 60 °C. The cDNA α probe hybridised to mRNA $\alpha\beta$ to 90% completion and contained approximately 10% cDNA β as determined by hybridisation to mRNA lacking α -globin sequences. The cDNA β probe hybridised to 80% completion and contained 12% cDNA α as determined by hybridisation to mRNA lacking β -globin sequences. 9S mRNA from the peripheral blood of WD was prepared by phenol-chloroform extraction followed by sucrose gradient sedimentation. 0.1 ng of cDNA α (○) or cDNA β (●) were mixed with increasing amounts of mRNA in 2 μ l of hybridisation buffer in a sealed siliconised glass capillary tube and incubated at 43 °C for 100 h. The amount of cDNA hybridised was determined after incubation with S₁ nuclease¹⁹. The ratio of mRNA β to mRNA α is equal to the mRNA/cDNA ratio at which 50% of the cDNA α is hybridised divided by the ratio at which 50% of the cDNA β is hybridised. The cDNA concentration is corrected for the maximum amount of hybridisable cDNA. 50% of cDNA α was hybridised at ratio of approximately 200:1, and 50% of cDNA β at 3:1, giving a mRNA β /mRNA α ratio of 65:1.

peripheral blood and marrow was normal. Approximately 95% of the red cells generated typical Hb H inclusions and haemoglobin analysis showed 50-65% Hb H. The genetic form of Hb H disease was excluded because WD had been shown to have a normal blood picture 10 yr previously and examination of his children showed no evidence of thalassaemia or defective α -chain synthesis. The ratio of α - to β -chain synthesis in the peripheral blood was 0.07 as measured by 3 H-leucine incorporation^{13,14}. In the genetic form of Hb H disease this ratio ranges from 0.3 to 0.62 with a mean of 0.5^{15,16}.

mRNA prepared from the peripheral blood was translated in the wheat germ cell free protein synthesis system and the product analysed by CM-cellulose chromatography¹⁷. The mRNA directed the synthesis of β chains but no α -chain synthesis could be detected. In a similar study using mRNA from five patients with the genetic form of Hb H disease the α/β -chain production ratio ranged from 0.05 to 0.25 (mean 0.16)¹⁷. To determine whether the absence of α -chain synthesis was due to the absence of mRNA α or due to an abnormal mRNA α , mRNA was hybridised to purified complementary cDNAs as described previously¹⁸ (Fig. 1). At low mRNA/cDNA ratios the cDNA α probe hybridised to approximately 10%, which represents the hybridisation of contaminating cDNA β sequences. The cDNA α probe continued to hybridise at a slow linear rate up to the maximum level of 90% hybridisation at very high mRNA/cDNA ratios, indicating that a small amount of intact mRNA α sequences were present in the mRNA. The mRNA β /mRNA α ratio was calculated to be 65:1 and hence the amount of mRNA α relative to mRNA β was 1.5%.

To determine whether the virtual absence of mRNA α resulted from a transcriptional defect or a deletion of the α -globin genes in the malignant cell line, the hybridisation

kinetics of cDNA_α in cDNA excess with DNA from the erythroid bone marrow of WD were compared with those of normal DNA^{18,19}. Figure 2 shows that the cDNA_α probe gave a similar hybridisation curve with both DNA species indicating that α-globin sequences were present in the DNA to the same extent as normal DNA. But, the cDNA_α probe is less than half the length of the α-globin gene and thus a gene deletion beyond the region of DNA complementary to the cDNA_α probe would not be observed. To check that a gene deletion in the region of DNA complementary to the cDNA_α probe could be detected in our experimental conditions, cDNA_α was hybridised in cDNA excess to DNA prepared from the liver of an infant with the Hb Bart's hydrops syndrome^{3,4} and to a mixture of equal amounts of hydrops DNA and normal DNA (Fig. 2). The cDNA_α hybridised to the mixture to half the extent seen with normal DNA and hybridised to the hydrops DNA to a lesser extent than the mixed DNA, showing only a very small rise above the background value. The plateau value of the amount of cDNA hybridised to DNA in cDNA excess was used to calculate the number of globin genes hybridising to the cDNA_α. Table 1 lists the results for the hybridisation curves shown in Fig. 2, together with results of other cDNA excess hybridisations (not shown) conducted as control experiments. These results indicate that there is no major deletion of the α-chain genes in the DNA of the abnormal cell line of WD. Furthermore, they confirm previous observations^{3,4} that the α-globin gene sequences are largely deleted in the Hb Bart's hydrops syndrome, that is, the homozygous state for α thal 1. The observed small amount of hybridisation of hydrops DNA (0.2 genes) to the cDNA_α probe can be accounted for by contamination of the cDNA_α probe with about 10% cDNA_β.

The deficit of α-chain synthesis in this patient with acquired Hb H disease was much more marked than that which is found in the genetic form of the disease. Indeed, there was probably no α-chain synthesis in the neoplastic red cell line. Thus the pattern of haemoglobin synthesis was very similar to that observed in the Hb Bart's hydrops syndrome²¹ except that in this case

Fig. 2 Hybridisation of human globin cDNA_α in cDNA excess to DNA from the bone marrow of WD, DNA from normal human spleen and DNA from Hb Bart's hydrops foetalis liver. DNA was prepared from cell nuclei by hydroxylapatite chromatography²¹ and sonicated to 200–300 nucleotides in length. cDNA_α 20 pg was mixed with 100 μg of DNA in 20 μl of 0.12 M sodium phosphate, pH 6.8 and sealed in a siliconised glass capillary tube. The mixtures were denatured for 10 min at 100 °C and annealed at 66 °C. At the appropriate times, the amount of cDNA hybridised was determined after incubation with S₁ nuclease¹⁹. The percentage of cDNA hybridised was converted to pg of cDNA hybridised using the formula described by Bishop and Freeman²⁰. The cDNA concentration is corrected for the maximum amount of hybridisable cDNA. The figure shows the hybridisation of cDNA_α in cDNA excess to DNA from the bone marrow of WD (●), normal DNA (○), hydrops DNA (△) and a mixture (■) of equal amounts of normal DNA and hydrops DNA.

Table 1 No. of globin genes per haploid genome as determined by cDNA excess hybridisations

cDNA	DNA	cDNA hybridised (pg)	Gene complexity	Gene no.
cDNA _α	WD, blood	5.0	90,000	1.5
cDNA _α	WD, bone marrow	5.6	101,000	1.6
cDNA _α	Normal	5.4	97,000	1.6
cDNA _α	Normal/hydrops	2.4	43,000	0.8
cDNA _α	Hydrops	0.5	9,000	0.2
cDNA _β	WD, Blood	7.2	130,000	1.9
cDNA _β	WD, Bone marrow	7.6	137,000	2.0
cDNA _β	Normal	8.1	146,000	2.1

cDNA excess hybridisations were performed as described in Fig. 2 legend. The gene complexity is calculated from the plateau value pg of cDNA hybridised per 100 μg DNA using the formula described by Bishop and Freeman²⁰. The gene number is equal to the gene complexity divided by the cDNA complexity (60,000 for cDNA_α, 70,000 for cDNA_β.)

β-chains were being produced instead of γ chains. Furthermore, unlike the Hb Bart's hydrops syndrome, the α-globin genes were intact in the neoplastic cell line in which α-chain synthesis was abolished. These findings suggest that there must have been a defect in α-chain gene transcription affecting both sets of haploid α-chain genes. One possible explanation is that there are specific repressors of the α-chain loci which are normally active only in embryonic life before α-chain synthesis commences, and that these repressors had been activated in the leukaemic cell line. This seems to be the most likely type of mechanism which could produce a *cis-trans* effect as evidenced by the suppression of both pairs of α-chain genes. There are examples of reversion to foetal erythropoiesis in leukaemia²² although regression to an earlier stage has not been reported. The lack of synthesis of embryonic ζ and ε chains in the abnormal cell line is incompatible with there having been a complete reversion to embryonic haemoglobin synthesis; the genetic mechanism which inhibited α-gene transcription was highly specific for the α-chain loci.

We thank Drs A. Pollock and M. J. Lewis, General Hospital, Birmingham, for allowing us to study this patient, and Professor Paul Polani and Dr M. G. Daker of Guy's Hospital for chromosome analysis. The work was supported by grants from the MRC and CRC.

Polymerisation of haemoglobin SA hybrid tetramers

ERYTHROCYTE sickling and gelation of concentrated solutions of deoxyhaemoglobin (Hb) S ($\alpha_2\beta_2^{6Val}$) results from helical polymerisation of the tetramers, with a spatial orientation approximated by recent ultrastructural and optical studies. Earlier observations of the gelling behaviour of Hb S or Hb C Harlem ($\alpha_2\beta_2^{6Val, 73Asn}$) mixed with Hb A or other haemoglobins gave indirect evidence concerning intertetrameric contact sites, and we proposed that only one $\beta 6$ valine-determined site was active per tetramer, the other β chain providing different polymer contacts^{1,2}. Our arguments required that asymmetrical hybrids (for example $\alpha_2\beta^A\beta^S$) occurred in Hb mixtures; their long-suspected presence has recently been established³⁻⁵, but the dissociation equilibria by which these hybrids form (Fig. 1) hinders their isolation and direct testing of their ability to polymerise. To circumvent this difficulty we have prepared Hb SA hybrids cross-linked intratetramERICALLY to prevent dissociation, and have found them capable of polymer and gel formation quite similar to that of Hb S.

Fig. 1 Comparison of hybrid tetramer formation with cross-linked haemoglobins. *a*, Formation and distribution at equilibrium of hybrid and non-hybrid tetramers in a 1:1 mixture of Hb S and Hb A. *b*, Cross-linked Hb S and Hb SA hybrids as prepared in the present experiments; the covalent cross-link between the α -chain amino termini prevents dissociation into $\alpha\beta$ dimers, stabilising the SA hybrid.

Haemoglobin S and mixtures of equimolar amounts of Hb S and Hb A were each reacted with the bifunctional cross-linking reagent, difluorodinitrophenylsulphone, as described by Macleod and Hill⁶, and the cross-linked tetramers were separated from unreacted haemoglobin by chromatography on Sephadex G-100 in 1 M $MgCl_2$. Isoelectric focusing of the cross-linked tetramer fraction of reacted Hb S alone showed only one major haemoglobin band, whereas the corresponding tetramer fraction from the Hb S-Hb A reaction mixture showed three distinct bands which were stable in the liganded (CO) state. One of these three bands corresponded in position to the cross-linked (CL-) Hb S, another to CL-Hb A; midway between those two was a more prominent band, not seen with the fractions from Hb S or Hb A alone, which represented the hybrid CL-Hb SA ($\alpha_2\beta^S\beta^A$). Preparative isoelectric focusing permitted complete separation of the bands of interest (Macleod and Hill had obtained three subfractions by ion-exchange chromatography of the tetramer fraction of their Hb SA reaction mixture, and they identified the middle fraction as a true S-A hybrid⁴. We observed (as they did) incomplete separation of the three fractions by their method; we therefore used isoelectric focusing

on a preparative scale, which achieved complete separation of the three fractions with the corresponding charge differences. Migrating anodal to the well defined bands on each gel was a diffuse zone of Hb which probably represented a variety of other cross-linked reaction products⁶). Although the corresponding subfractions were shown by Macleod and Hill to be heterogeneous, including tetramers with unidentified cross-links between $\alpha\beta$ dimers together with the major product cross-linked between the α -chain amino termini, our present experiments required only the isolation of a stable non-dissociating $\alpha_2\beta^S\beta^A$ fraction free from $\alpha_2\beta_2^S$. (Some CL-Hb S was obtained from the major band of focused gels for which the starting material was Hb S alone rather than the Hb S-Hb A mixture. As noted, this major band coincided with the cathodal band on gels of the S-A mixtures. After the gelling experiments the CL-Hb S and CL-Hb SA hybrids were re-examined by isoelectric focusing each alone and both mixed together. Although all the steps in handling resulted in some charge-heterogeneity in each sample, none of the CL-Hb S bands co-focused with the CL-Hb SA bands, confirming the absence of contamination of CL-Hb SA by any detectable form of $\alpha_2\beta_2^S$.) The gel bands were sliced and the Hb fractions, eluted by the technique of Suzuki *et al.*⁷, and stored in the CO-form in liquid N_2 . When sufficient material was accumulated, the CL-Hb S and CL-Hb SA were converted from the CO-form to the cyanmet form (to permit rapid conversion by dithionite into deoxy Hb) and minimum gelling concentrations (MGCs) were determined in duplicate, as previously described¹ with the following minor modifications: 300- μ l aliquots of Hb solution were equilibrated with N_2 in 5 ml Erlenmeyer flasks, and the cyanmethaemoglobin was converted to the deoxy form by anaerobic addition of sodium dithionite (2 mol per mol total haem). Both the CL-Hb S and CL-Hb SA gelled, liquified on chilling the flask in an ice bath and gelled on subsequent re-warming to room temperature, as occurs with native Hb S. The MGC values and other details of the experimental conditions are shown in Table 1. Following gelation the chilled duplicate samples were combined and transferred anaerobically to centrifuge tubes under oil, allowed to gel again by equilibration at room temperature and centrifuged at 25 °C for 120 min at 122,000*g* (in a Beckman L3-50 centrifuge using an SW65K rotor) to sediment the solid phase. The supernatant concentrations, representing polymer solubility⁸, were 25.6 g Hb dl⁻¹ for CL-Hb S and 28.7 g Hb dl⁻¹ for CL-Hb SA. The supernatants were decanted and portions of the packed solid phases were fixed in deoxygenated solutions of 3% glutaraldehyde. After osmication and dehydration, the pellets were embedded in Epon 812. Examination of ultrathin sections by electron microscopy revealed 'polymer' rods in the solid phases of both CL-Hb S and CL-Hb SA which were irregularly distributed in all directions, measured 165-175 Å in diameter, and were indistinguishable from those seen by us and others in sections of deoxygenated sickle (SS) cells.

These findings show that the hybrid tetramers $\alpha_2\beta^S\beta^A$ are capable of gelation and polymerisation which is similar or identical to that of Hb S. Conformational changes in the cross-linked Hb, as indicated by its abnormal respiratory functions (high oxygen affinity and loss of cooperativity in oxygen binding)⁶ must account for the higher MGC value for CL-Hb S as compared with native Hb S. The CL-Hb S may, nevertheless, serve as a control for comparison with the gelling behaviour of the CL-Hb SA. Having established that only one

Table 1 MGC values of cross-linked Hb SA hybrids compared with cross-linked and native Hb S

Native Hb S ($\alpha_2\beta_2^S$)	22.2
CL-Hb S	27.3
CL-Hb SA ($\alpha_2\beta^S\beta^A$)	30.8

Haemoglobin dialysed against 0.15 M potassium phosphate, pH 7.35, deoxygenated with N_2 gas at 25 °C, sodium dithionite added; final pH of Hb 6.9-7.0; mean MGC values expressed in g Hb dl⁻¹.

β^S chain per tetramer is required for polymerisation, we predict that Hb SA hybrids would have a smaller tendency to polymerise than Hb S tetramers. Compared with Hb S, which should be capable of fitting into the helical polymer in either of two symmetrical orientations (with either β^S chain providing the intermolecular binding site determined by the β^6 valine substitution), the SA hybrids would be expected to exhibit some steric hindrance for entry into the polymer, resulting in $k_1 > h_1$ in the following equilibria

There is reason to believe that the non-S β chain (or non-'active' β^S chain) of a tetramer provides other contacts in the polymer involving the regions of β^73 (E 17) and β^121 (GH4), but not the N-terminal region^{9,10} so that the forces maintaining the Hb S and Hb SA polymers, reflected in k_2 and h_2 , may be similar. In this case, the differences we have observed in both the MGC and polymer solubility values for CL-Hb S and CL-Hb SA reflect the expected differences in k_1 and h_1 described above.

By mixing haemoglobins in the deoxy state or by covalently cross-linking Hb A or Hb F tetramers (by the methods of Macleod and Hill) to prevent hybrid formation in Hb mixtures, we have previously shown that the well known inhibitory effect of Hb F on gelation of Hb S requires formation of $\alpha_2\beta^S\gamma$ hybrid tetramers; in contrast, the presence or absence of hybrid formation in mixtures of Hb S with Hb A had no net effect on the minimum gelling concentration¹¹. Similar results and conclusions were subsequently described by Goldberg *et al.*¹² who centrifuged the gels as an assay of polymer solubility. The differences in MGC and polymer solubility values of CL-Hb S and CL-Hb SA observed in our study are qualitatively consistent with our proposed explanation for the equivalent gelling tendencies of mixtures of Hb S and Hb A in which hybrid formation was permitted or prevented¹¹.

It is not yet clear whether or not Hb tetramers containing no β^S chains, such as Hb A or Hb F, are capable of entering the polymer. Our previous results suggested that these non-S tetramers facilitated gelling in a less specific manner¹¹ but the available evidence concerning this issue is quite indirect, and partially conflicting¹². Our results provide direct evidence that Hb SA hybrids can enter the polymer in place of Hb S tetramers, but with somewhat less efficiency than Hb S.

The mechanism by which actinomycin D inhibits protein synthesis in animal cells

In the course of studies on the regulation of protein synthesis during the activation of human lymphocytes by phytohaemagglutinin (PHA), it became necessary to determine whether an effect which occurred following treatment with actinomycin D (AMD) was secondary to the action of the drug on transcription, or resulted from a direct effect on translation. Using enucleated lymphocytes, we have shown that AMD has no effect on protein synthesis in the absence of the cell nucleus and conclude that AMD interferes with protein synthesis by its effect on transcription of RNA.

AMD is a potent inhibitor of RNA synthesis in eukaryotic cells¹ and is widely used by molecular biologists. Protein synthesis diminishes in cells treated with AMD (refs 2, 3) and this was originally attributed to decay of messenger RNA (mRNA), but more recent findings have made that view untenable⁴⁻⁷. An additional effect of the drug, at the level of initiation of protein synthesis, has therefore been proposed, although the mechanism of this putative action has not been elucidated^{4,5}. In particular, it remains uncertain whether AMD inhibits protein synthesis by preventing the synthesis of some RNA component, other than mRNA, or by a direct action on the initiation of translation. Because of this uncertainty, the interpretation of much published data is subject to doubt.

To clarify this question, lymphocytes were enucleated by treatment with cytochalasin B followed by centrifugation in a density gradient as described by Wigler and Weinstein⁸. Lymphocyte cytoplasts produced in this way continued to incorporate ³H-leucine into acid-insoluble material for several hours (Fig. 1a). Since this incorporation was inhibited by puromycin (Fig. 1a), the action of which requires peptide bond formation⁹, we conclude that protein synthesis was occurring in cytoplasts by the normal mechanism. Cycloheximide, which inhibits protein synthesis by a different mechanism¹⁰, was also effective (results not shown). Cytoplasts prepared from lymphocytes previously stimulated by PHA for 16 h showed a ninefold higher rate of incorporation of amino acids than those from resting cells, reflecting the difference in protein synthetic activity commonly seen between resting and growing lymphocytes (Fig. 1b).

Addition of AMD to cytoplasts from either resting or growing lymphocytes had no effect on protein synthesis (Fig. 1b). Treatment of intact lymphocytes, either resting or growing, with AMD caused a diminution of protein synthesis, with progressive reduction in the incorporation of amino acids (Fig. 2a). Treatment of intact cells with cytochalasin B, in a manner similar to that used for producing cytoplasts, did not itself interfere with protein synthesis, nor did it prevent the inhibition of protein synthesis by AMD (Fig. 2b).

Inhibition of protein synthesis by AMD in resting and growing lymphocytes thus only occurs in nucleated cells. If a direct effect of AMD on translation occurred, it should be detectable in cytoplasts as well. Since it was not, we conclude that AMD inhibits protein synthesis in lymphocytes as a consequence of its well known action on nuclear RNA synthesis, and not by any direct action on translation. If the only action of AMD were functionally to enucleate the cell with respect to RNA synthesis, it follows that its effect on protein synthesis should be equivalent to mechanical enucleation. This hypothesis was

The upper layer of cytoplasts was aspirated, diluted with MEM and sedimented at 1,000g for 15 min. Cytoplasts were resuspended in MEM containing 1/20th the usual concentration of amino acids plus 2% autologous plasma, and incubated (37 °C) with ^3H -leucine (Schwarz-Mann, 50 Ci mmol^{-1} , 10 $\mu\text{Ci ml}^{-1}$). At the times indicated, duplicate 1.0-ml samples were applied to GF/C filters moistened with phosphate-buffered saline (PBS) containing unlabelled leucine and washed first with PBS-leucine under gentle suction, then with cold 5% trichloroacetic acid-leucine. After drying, radioactivity remaining on the filter was measured by liquid scintillation counting. The RNA content of the suspensions was measured by precipitation with cold 2% perchloric acid (PCA) (10 min), washing with cold 2% PCA, digestion in 10% PCA at room temperature for 17 h, removal of insoluble material by centrifugation and measurement of A_{260} , using $E_{1\%}^{1\text{cm}} = 320$. Results were expressed as c.p.m. μg^{-1} RNA. No correction was made for radioactivity in leucyl-tRNA, as previous experiments showed the contribution from this source to be negligible. *a*, Effect of puromycin on amino acid incorporation: ●, untreated cytoplasts from resting lymphocytes; ○, 100 $\mu\text{g ml}^{-1}$ puromycin added 5 min before addition of ^3H -leucine. *b*, Effect of actinomycin D on protein synthesis by cytoplasts: ●, resting-cell cytoplasts, no AMD; ○, resting-cell cytoplasts, 1 mg μl^{-1} AMD added with ^3H -leucine. ■, Cytoplasts from lymphocytes incubated 16 h with PHA (5 $\mu\text{g ml}^{-1}$), no AMD; □, growing-cell cytoplasts, 1 $\mu\text{g ml}^{-1}$ AMD added.

supported by a comparison between data from several experiments with cytoplasts and with AMD-treated intact cells (Fig. 2c). The two sets of data showed no significant difference in the kinetics which characterise the progressive fall in protein synthesis.

It has been reported previously that at least 50% of newly-synthesised mRNA (cytoplasmic RNA⁺ poly(A)) in resting lymphocytes is very short lived, with a half life of the order of 20 min, whereas the remainder of newly synthesised mRNA is highly stable, with a half life in excess of 20 h (ref. 11). Using this information, and assuming a minimum half life for stable mRNA of 20 h, it may be calculated that the steady-state level of labile mRNA in non-growing lymphocytes is on the order of 2% of the total, the remainder being highly stable. It is

likely, therefore, that AMD interferes with translation by abolishing the synthesis of some RNA species other than mRNA⁺ poly(A), since the small contribution of labile mRNA to the steady-state total would not account for the effect of the drug.

Lymphocyte protein synthesis is virtually unaffected by concentrations of AMD which specifically inhibit rRNA synthesis¹², and ribosomal 5S RNA synthesis is not abolished by such low concentrations of AMD, but its appearance in the cytoplasm is prevented¹³. Since this deficiency is not associated with diminished protein synthesis, it is evident that interruption in the supply of new 5S RNA to the cytoplasm is not the means by which higher concentrations of AMD inhibit protein synthesis. Craig³ dismissed reduced tRNA synthesis as a possible cause

Fig. 2 Effect of actinomycin D on protein synthesis by intact lymphocytes. Lymphocytes were suspended at $2 \times 10^6 \text{ ml}^{-1}$ in MEM, 1/20th amino acid concentration, 2% autologous plasma and incubated with ^3H -leucine (10 $\mu\text{Ci ml}^{-1}$). Cell collection and analysis were as in Fig. 1. *a*, Effect of AMD on protein synthesis in resting and growing lymphocytes: ●, resting lymphocytes, no AMD; ○, resting lymphocytes, 1 $\mu\text{g ml}^{-1}$ AMD added at zero time; ■, PHA, 16 h before labelling, no AMD; □, PHA, 16 h, AMD, 1 $\mu\text{g ml}^{-1}$, added at zero time. *b*, Effect of cytochalasin pretreatment on protein synthesis by intact lymphocytes. Resting cells were incubated for 1 h with 10 $\mu\text{g ml}^{-1}$ cytochalasin B in MEM, 10% autologous plasma, then centrifuged and resuspended in labelling medium. ●, No CB treatment; ▲, CB-treated cells; ○, CB-treated cells, 1 $\mu\text{g ml}^{-1}$ AMD added with ^3H -leucine. *c*, Comparison of kinetics of amino acid incorporation in resting-cell cytoplasts with those of intact resting cells treated with AMD. for inhibition of protein synthesis in AMD-treated L cells because 8 h of exposure to $0.25 \mu\text{g ml}^{-1}$ AMD caused a 50% reduction in protein synthesis. This concentration of the drug was thought to be too low to inhibit tRNA synthesis. No actual data were given to demonstrate unimpeded tRNA synthesis, however, and in our view, tRNA has not been eliminated as the critical molecule whose synthesis, when interrupted by AMD, causes cessation of protein synthesis. This thesis is presently being examined, together with the more general proposition that availability of tRNA may have a regulatory role in governing the rate of protein synthesis in resting lymphocytes.

Regulation of maternal mRNA translation in developing embryos of the surf clam *Spisula solidissima*

MESSANGER RNA not bound to ribosomes (non-polysomal mRNA) has been found in the cytoplasm of sea urchin^{1–3} and *Spisula solidissima* eggs⁴. The mRNA synthesised and stored during oogenesis (maternal mRNA) is utilised when protein synthesis is activated by fertilisation. Translation of maternal mRNA allows sea urchin embryos to proceed through several cellular divisions even when synthesis of embryonic mRNA is blocked by actinomycin D^{5–6}. But, embryonic mRNA is synthesised soon after fertilisation and already translated at the early cleavage stage⁷. Qualitative and quantitative changes in the pattern of histone synthesis during sea urchin embryogenesis have suggested that the synthesis of these proteins is temporally regulated in the embryo and that different mRNA species are translated at successive stages of embryo development⁸. We report here that part of the mRNA is found unassociated with ribosomes in eight-cell embryos of *S. solidissima*. Some of the translation products of this non-polysomal mRNA are different from those of polysomal mRNA, but identical to translation products of maternal mRNA isolated from eggs. This suggests that part of the non-polysomal mRNA of embryos consists of maternal mRNA species which are inefficiently translated after fertilisation.

Cytoplasmic extracts of *S. solidissima* embryos were fractionated by centrifugation on sucrose gradients (Fig. 1). The RNA isolated from the polysome pellet and from gradient fractions was translated in the wheat germ cell-free system⁹. Polysomal RNA and the RNA extracted from a cytoplasmic fraction sedimenting between 20S and 60S (non-polysomal mRNA) significantly stimulated protein synthesis and were

Fig. 1 Fractionation of *S. solidissima* eight-cell embryos homogenate by centrifugation on sucrose gradient. Eggs were collected, washed and fertilised⁴ and embryos were collected by centrifugation and washed as described before⁴. One volume of packed embryos was homogenised with 4 volumes of TNM (20 mM Tris-HCl pH 7.6, 0.2 M NaCl and 5 mM magnesium acetate). The homogenate was centrifuged for 10 min at 12,000 r.p.m. and 4.5 ml of the supernatant were fractionated by 19 h centrifugation at 26,000 r.p.m. through a 34-ml 20–40% sucrose gradient in TNM. The gradients were monitored for A_{260} (solid line) and subdivided into four fractions. Polysomes were recovered in the pellet. RNA was obtained from gradient fractions and from the polysome pellet by phenol extraction and ethanol precipitation¹⁷. The RNA was assayed in a wheat germ cell-free system prepared according to Roberts and Patterson⁹. Each fraction was tested at several RNA concentrations and the stimulation of protein synthesis measured by the incorporation of ³H-lysine into protein in 60-min incubations as previously described¹⁷. The activity of each fraction was calculated from a range of concentrations which gave a stimulation of protein synthesis proportional to the input of RNA. The activity of each fraction is expressed as c.p.m. $\times 10^{-3}$ per μg RNA. Twenty mg of RNA were recovered from the polysome pellet and 5.3 were recovered from fraction III per ml of packed embryos fractionated. Taking into account the relative stimulatory activity and the amount of RNA recovered, it was calculated that the total template activity of polysomal RNA was four times that of fraction III RNA.

directly used in subsequent experiments. About 80% of the template activity of embryo RNA was found in the polysome pellet, and the remaining 20% was found in the fraction sedimenting at 20–60S (Fig. 1).

The translation products of polysomal and non-polysomal embryo mRNA were compared with those of mRNA obtained from whole eggs and purified by absorption of oligo (dT)-cellulose¹⁰. The translation products were fractionated by electrophoresis on polyacrylamide gels containing sodium dodecylsulphate (SDS)¹¹ and detected by fluorography¹² (Fig. 2). The translation products of embryo polysomal mRNA correspond predominantly to marker histones. But, the products of embryo non-polysomal mRNA show in addition to histones some bands which are not detected among the translation products of polysomal mRNA (indicated by arrows in Fig. 2). The translation products of egg mRNA show two bands corresponding to histones H1, several poorly resolved bands migrating with or slightly faster than marker histones, and other bands corresponding to translation products of both polysomal and non-polysomal embryo mRNA. Aliquots of each translation assay were extracted with 0.2 M H_2SO_4 (ref. 13) to further purify histones. The proteins extracted with acid were fractionated by SDS gel electrophoresis (Fig. 2). This analysis showed that

Fig. 2 Analysis of the translation products of polysomal and non-polysomal embryo RNA and of egg RNA. Embryo RNA was prepared as described in Fig. 1. RNA was obtained from eggs homogenised with 4 volumes of TNM, centrifuged 10 min at 12,000 r.p.m., made 1% in SDS and extracted with phenol¹⁷. The RNA was chromatographed on oligo(dT)-cellulose¹⁰ and the poly(A)-containing fraction used for translation assays. The RNA was translated with wheat germ extract containing 0.88 mCi ml⁻¹ of ³H-lysine (40 Ci mol⁻¹). Aliquots of each incubation were analysed by electrophoresis on 12.5% polyacrylamide gels containing SDS¹¹. The radioactive proteins were detected by fluorography of the dried gels¹². The position of marker histones from developing embryos⁴ is shown schematically on the left. Track 1, translation products of polysomal embryo RNA; 2, translation products of fraction III non-polysomal RNA (see Fig. 1); track 3, translation products of egg RNA. An aliquot of each assay was treated with 0.2 M H₂SO₄ to extract the acid-soluble proteins¹³, which were then precipitated with 4 volumes of ethanol and analysed in parallel. Tracks 4, 5 and 6, acid-soluble proteins prepared from the translation assays analysed in tracks 1, 2 and 3, respectively. Track 7, marker H1 histones purified from developing eight-cell embryos incubated with ¹⁴C-lysine⁴; the H1 histones were isolated by precipitating the other histones with 5% perchloric acid²¹. The arrows on the left indicate bands present among the translation products of non-polysomal embryo RNA and of egg RNA.

all the embryo and egg peptides co-migrating with marker histones are acid extractable. Among the egg mRNA translation products, histones H1 are clearly identified, whereas other histones are present in relatively lower amounts. In subsequent experiments egg and embryo RNA were fractionated in parallel into size classes by centrifugation on sucrose gradients (Fig. 3). The RNA sedimenting between 4 and 18S, which is enriched in histone mRNA¹, was isolated and translated in the wheat germ cell-free system. The translation products of 4–18S RNA were analysed by electrophoresis in a gel system devised for the fractionation of histones, which separates proteins primarily on the basis of their charge¹⁴. The two H1 histones, which separate in SDS gel electrophoresis, migrate together in this gel system (Fig. 3). The translation product of 4–18S egg RNA contain H1 histone and two additional peptides, which correspond to translation products of embryo mRNA. One peptide migrates like H4 histone and the other between marker H2A and H1 histones. This peptide also appears among the translation products of embryo non-polysomal mRNA, but not among the products of embryo 4–18S polysomal mRNA (Fig. 3). This peptide represents one further example of a maternal template which is found among non-polysomal mRNA species in the embryo.

The translation products of egg mRNA isolated by oligo(dT)-cellulose chromatography were also analysed in the gel system described above (Fig. 3). By overloading the gel it was possible to show that egg RNA codes for the other histones in addition to H1 histones. This suggests that mRNAs for all histones are present in *S. solidissima* eggs, though in quite different relative amounts, and that these mRNAs may contain poly(A) since they bind to oligo(dT)-cellulose. Histone mRNA obtained from *Xenopus*¹³ and *Triturus*¹⁵ eggs contain poly(A), whereas histone mRNA

obtained from mammalian cells does not contain poly(A)¹⁵ and does not bind to oligo(dT)-cellulose¹⁰.

The analysis of mRNA distribution in eight-cell embryos of *S. solidissima* shows that part of the mRNA is not associated with polysomes and therefore is not actively translated at this stage of development. We have only examined in detail the RNA distribution in eight-cell embryos. In older embryos there is less non-polysomal mRNA (our unpublished observations), whereas in eggs most of the mRNA is non-polysomal¹. A simple interpretation of these observations is that during embryonic development maternal mRNA is translated in an orderly fashion. In the eight-cell embryo some mRNA species are preferentially translated, whereas others are not translated and are therefore found as non-polysomal mRNA species. We have no evidence that these non-polysomal mRNA species are translated later in embryogenesis, though this seems in view of the decrease in non-polysomal mRNA. We suggest, however, that the presence of non-polysomal mRNA is due to translational regulation in eight-cell embryos. Translation of maternal and newly synthesised mRNAs may be regulated in a specific way. This regulation does not involve the activation of maternal templates by addition of the 5'-terminus m⁷Gppp (ref. 17), since *S. solidissima* egg mRNAs already contain this structure (unpublished).

Various mechanisms have been proposed to explain translational regulation (see ref. 18 for review). These mechanisms can be subdivided into two types: (1) regulation involves a change in the components of the translational machinery; (2) regulation results from changes in the species of mRNA present and/or in the activity of the cell to initiate synthesis of new polypeptides. Our experiments have not been directed at studying the mechanisms of translational regulation operating in embryos. An analysis of the events which take place on fertilisation makes it possible, however, to propose an interpretation of the regulatory pattern observed.

The predominant templates translated by embryos are histone mRNAs (Fig. 1). These templates are present in relatively small amounts among maternal mRNA species, with the exception of H1 histone mRNA⁴. Active synthesis of histone mRNA on fertilisation is necessary to account

Fig. 3 Analysis of the translation products of embryo and egg RNA. The translation assays are described in Figs 1 and 2. Proteins were fractionated on 12% polyacrylamide gels containing 7.5 M urea, 6 mM Triton X-100, and 0.9 M acetic acid¹⁴. The proteins were detected by fluorography¹². Tracks 1 and 3, translation products of egg RNA containing poly(A) and of fraction III non-polysomal embryo RNA (see Fig. 1). The egg RNA and polysomal embryo RNA were fractionated by centrifugation on sucrose gradients^{1,17} and the fractions containing RNA sedimenting between 4S and 18S pooled. Track 2, translation products of 4–18S egg RNA; track 4, translation products of 4–18S polysomal embryo RNA. Track 5, marker H1 histones prepared as described in Fig. 2. The arrow at the right indicates a prominent band which is found among the translation products of egg 4–18S and of embryo non-polysomal RNA. The position of marker histones prepared from developing embryos⁴ is indicated on the right.

for the synthesis of histones in embryos. Synthesis of mRNA with the sedimentation characteristics of histone mRNA has indeed been reported in *S. solidissima* embryos¹⁹. The presence of histone mRNA among the non-polysomal mRNA species (Fig. 2) suggests that the supply of mRNA exceeds the capacity of the eight-cell embryos to translate this mRNA. This situation leads to competition among different mRNA species for translation. Histone mRNA is one of the 'strongest' mRNA molecules. Treatments of HeLa cells which result in competition among mRNAs for translation suppress the synthesis of most cellular proteins except histone²⁰. The translational regulation observed in *S. solidissima* embryos may be based on a similar mechanism. Initiation may be the limiting step in protein synthesis in embryos and this may lead to competition among different mRNAs for translation. Histone mRNA may therefore be preferentially translated over other 'weaker' mRNAs, which are presumably translated later in development, when initiation is no longer limiting. This regulatory model does not involve any qualitative change in the components of the translational machinery, but only an increase in the activity of embryos to initiate protein synthesis.

Variability of DNA content of murine fibrosarcoma cells

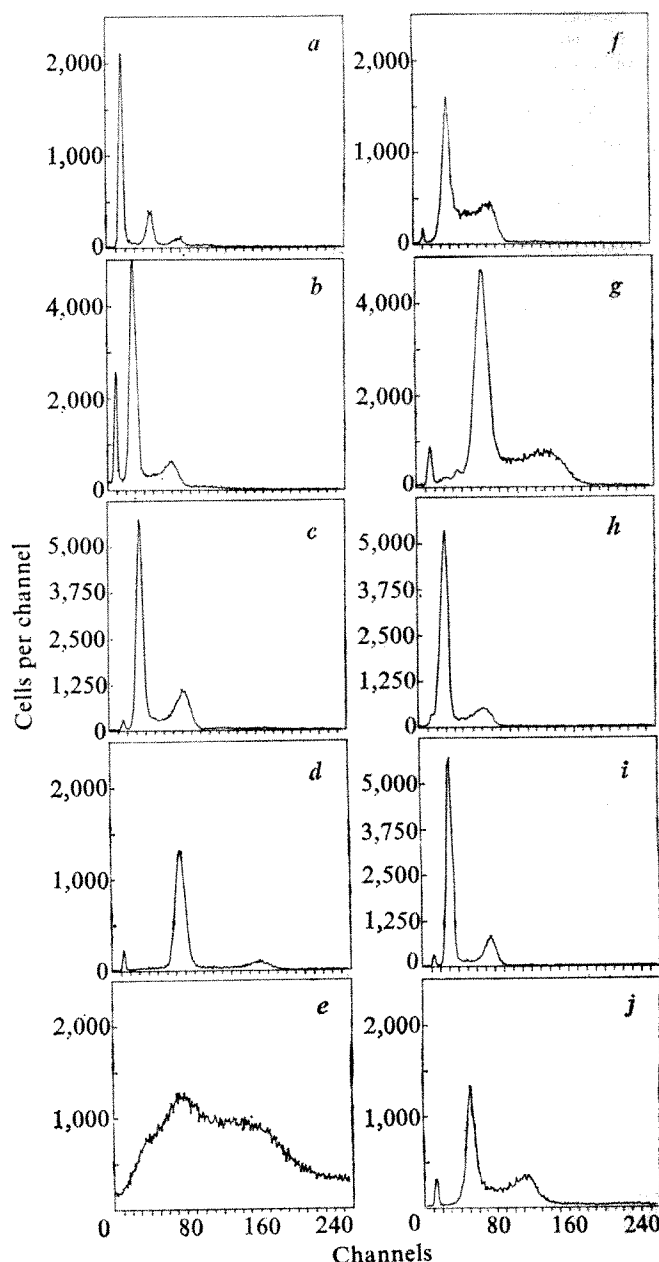

ANEUPLOIDY or heteroploidy and hyperploidy have been observed in tumours of experimental animals and of humans and seem to be a feature of most malignant cells¹⁻⁹. DNA contents seem to correlate with karyotype in these changes or deviations from euploidy. Most tumours are hyperploid and higher in DNA content^{2,8,9}. A rapid and reliable method of analysis of DNA content distribution of a cell population has recently become available with the development of flow microfluorometry (FMF)¹⁰. We report here the use of FMF analysis to measure

DNA content of clones isolated from a fibrosarcoma. All the clones examined had a higher DNA content than did either the normal cells tested or the original fibrosarcoma. There is thus a variability of DNA content in fibrosarcoma cells. This suggests that variability, as well as increase in DNA content in malignant cells may relate to their neoplastic development.

The clones FSA 1231, 1233, 1235, 12310, 12313, 12314, 12316, 12317, and 12318 were isolated from a methycholanthrene-induced fibrosarcoma by repeated cloning in soft agar medium¹¹ under selective pressure for enhanced clonogenicity (N.S. and H.R.W. *J. natn. Cancer Inst.* in the press). The surviving fraction of the original tumour cells was 10^{-7} to 10^{-6} , compared with 0.1 to 0.5 for the resulting highly clonogenic cells. The cells were cultured in a humidified CO₂ incubator with McCoy's 5A medium as modified by Hsu and containing 20% foetal calf serum.

The method of FMF analysis has been described elsewhere¹²⁻¹⁴. Briefly, 2 to 5×10^6 exponentially growing cells or

Fig. 1 Histogram of DNA content distribution obtained using flow microfluorometry. FSA 1231 (c), 1233 (d), 12310 (e), 12313 (f), 12314 (g), 12316 (h), 12317 (i), 12318 (j) were added with normal spleen cells. The spleen peak of FSA 12316 is seen only as a notch, since it includes only a small amount of spleen cells. This was done to avoid an effect on the G₁ peak of the sample. a. Spleen cells; b. FSA original cells.

tumour cells were fixed with 70% ethanol and stained with mithramycin (Pfizer) for DNA. The staining solution contained 50 $\mu\text{g ml}^{-1}$ mithramycin and 7.5 mM MgCl_2 in 12.5% aqueous ethanol. The flow microfluorometer was of the type described by Steinkamp *et al.*¹⁰

Quantitation and comparison of DNA content were carried out by adding spleen cell suspensions to each sample. The spleen cell suspensions were made from normal untreated $\text{C}_3\text{Hf/Bu}$ mice from the specific pathogen-free breeding colony maintained at the M. D. Anderson Hospital, Section of Experimental Radiotherapy. The minced spleen tissues were filtered through a stainless steel mesh (200 wires per inch) screen and washed by centrifugation. The suspension included singlet, doublet and triplet aggregates of spleen cells (Fig. 1). When the relative DNA contents for singlets, doublets and triplets were assigned values of 1, 2 and 3, and were plotted on a linear scale against channel number, a straight line relationship was observed. The line extrapolated across the abscissa at a certain point. This intercept value (channel number) was used to correct zero offset.

Figure 1 represents typical histograms of DNA content in various clones. Spleen cells were added as a standard to each sample except that from the original fibrosarcoma (tumour cell suspension) and FSA 12310. The position of the peak for normal cells in the original fibrosarcoma was not affected by addition of spleen cells although its height was increased, that is, DNA content of normal cells (G_1 peak) in a tumour was the same as that of spleen cells. Intrinsic normal cells were therefore used as a standard. G_1 peak positions of these clones were different from one another. Furthermore, FSA 12310 was completely heterogeneous with respect to DNA content.

Table 1 shows the relative DNA content (G_1 peak) of the various clones relative to spleen cells. These ratios were calculated from the modal G_1 peak positions after correction for zero offset. Modal peak positions were determined from digital records of cell number for each channel. Relative DNA content ranged between 1.49 and 3.07, while the relative DNA content of the original fibrosarcoma was 1.45. All clones so far examined have shown a relative DNA content greater than 1.0, that is, they contained more DNA than did normal cells. DNA content in all except FSA 12310 has remained stable through cell divisions after *in vitro* and *in vivo* growth suggesting a hereditary nature of the DNA content.

The coefficients of variation (c.v., 100 times the standard deviation divided by the mean) of G_1 peaks shown in Fig. 1, were 7.7 (FSA original), 6.8 (FSA 1231), 6.1 (FSA 1233), 8.8 (FSA 12313), 8.5 (FSA 12314), 9.7 (FSA 12316), 6.0 (FSA 12317), 7.3 (FSA 12318), and 5.8 ± 0.3 (spleen cells, \pm s.e. of the mean of eight measurements). The c.v. values of G_1 peaks of the original fibrosarcoma and of these clones were relatively large compared with that of normal spleen cells. The difference between some clones (FSA 1233 and FSA 12317) and spleen cells is not obvious, however.

Kramer *et al.* have investigated DNA content distribution of various established cell lines *in vitro* using FMF^{15,16}. They used c.v. of the G_1 peak to evaluate the heterogeneity of DNA content distribution in cell populations. They reported that DNA content by modal peak position of malignant cells was higher than that of normal cells. Surprisingly, however, the c.v. of the G_1 peak was not greater for malignant than for normal cells, even if a heterogeneity in the karyotype was observed. Thus, they concluded that DNA content distributions of malignant cells were not heterogeneous even if the karyotypes were, and that a change in karyotype does not always reflect an alteration in the DNA content of the cell. This conclusion challenges the classical view of the genetic entity of the chromosome.

We examined, using freshly isolated clones from a fibrosarcoma, whether DNA content of malignant cells varies and/or is greater than that in normal cells. In summary, our results lead us to conclude that these clones from a mouse fibrosarcoma were heterogeneous in DNA content implying that the cells had the ability to vary DNA content. All the clones derived by selective cloning and examined thus far have had a higher DNA content than the original fibrosarcoma cells. The results concerning DNA

Table 1 Relative DNA content of G_1 peaks of various clones

Cells	Relative DNA content	Mean \pm s.e.
FSA original	1.45	—
FSA 1231	1.61, 1.50	1.56 \pm 0.05
FSA 1233	3.03, 3.10	3.07 \pm 0.03

FSA 12312	1.60	—
FSA 12313	1.93, 2.00, 1.90	1.94 \pm 0.03
FSA 12314	2.84, 2.87, 2.80	2.84 \pm 0.02
FSA 12316	1.50, 1.44, 1.52	1.49 \pm 0.02
FSA 12317	1.62	—
FSA 12318	2.39	—

Relative DNA content is given relative to the spleen singlet peak (G_1) which was assigned a value of 1.

content from this system are consistent with the accumulated findings of aneuploidy and hyperploidy in karyotypes of malignant cells¹⁻⁷. Since higher cellular DNA content was found in clones selected for higher plating efficiency in adverse growth conditions *in vitro*, changes in ploidy during tumour progression¹⁻⁷ may reflect a similar selection process in the host.

Use of coupled transcription and translation to study mRNA production by vaccinia cores

VACCINIA is a double-stranded DNA virus which replicates in the cytoplasm of animal cells. Soon after infection, the outer layers of the virion are removed to yield core particles¹ which make mRNA that is transcribed, capped² and polyadenylated³ by enzymes present in the cores. Later, the cores break down, DNA synthesis begins, and 'late' genes are expressed⁴. Cores can be made *in vitro* by treating virions with non-ionic detergent and mercapto-ethanol. When incubated with nucleoside triphosphates, these particles produce mRNA⁵ which can be translated in cell-free systems to yield authentic vaccinia early proteins^{3,6,7}. It has recently been suggested that this mRNA may be derived from large primary transcripts⁸ which are processed in a manner similar to that proposed for cellular mRNA^{9,10}. I have obtained evidence that early vaccinia

mRNA is made by monocistronic transcription *in vitro*, by comparing the relative sensitivity of the synthesis of individual messages to ultraviolet irradiation. Production of mRNA was assayed indirectly using a coupled cell-free transcription-translation system in which protein synthesis is dependent on added vaccinia cores.

The use of partial ultraviolet inactivation to study transcription depends on the observation that the thymine dimers produced by irradiation cause premature termination of transcription¹¹. Assuming that all DNA is equally susceptible to ultraviolet damage, the sensitivity of synthesis of a given mRNA is proportional to the distance between its promoter and the 3' end of the cistron. In the case of messages which are primary transcripts, the ultraviolet sensitivity should be directly proportional to the length of the mRNA. This would clearly not be the case if several mRNAs were transcribed in tandem from a single promoter. Polycistronic transcription of the latter kind has been detected by ultraviolet irradiation experiments in DNA bacteriophages^{12,13}, adenovirus¹⁴, and the negative strand RNA viruses, vesicular stomatitis virus (VSV)^{15,16} and Sendai¹⁷.

The coupled transcription-translation system used in these experiments is based on the nuclease-treated reticulocyte lysate described previously¹⁸. Fig. 1 shows that when vaccinia cores are added to this system at concentrations similar to those found in infected cells, rapid synthesis of RNA begins after a brief lag. Protein synthesis starts after a further 5–10 min and continues linearly for

Fig. 1 RNA and protein synthesis directed by vaccinia virus cores in the nuclease-treated reticulocyte lysate. mRNA-dependent reticulocyte lysate prepared as described previously¹⁸ was supplemented by addition of 1 mM each of ATP, GTP, and CTP, 3.5 mM MgCl₂, 60 µg ml⁻¹ mouse liver tRNA, 2 mM glucose and either 20 µM methionine and 50 µM ³H-UTP (10.2 Ci mmol⁻¹) or 1 mM UTP and ³⁵S-methionine (4 × 10⁶ c.p.m. ml⁻¹; about 30 Ci mmol⁻¹ taking into account the unlabelled methionine present in the lysate). Cores, prepared as in ref. 5, were kindly provided by Jane Sykes, and were added at approximately 1.5 × 10¹⁰ ml⁻¹. Samples (5 µl) were removed at intervals for the assay of RNA synthesis by precipitation with cetyltrimethylammonium bromide (CTAB)²¹, or for protein synthesis as described previously¹⁸. Incubation temperature was 30 °C. ■, ³H-UTP incorporation; ●, ³⁵S-methionine incorporation; ○, ³⁵S-methionine incorporation in the presence of 7 µg ml⁻¹ actinomycin D.

Fig. 2 Protein synthesis directed by ultraviolet-irradiated vaccinia cores. Drops (1 µl) containing (2–3) × 10⁸ vaccinia cores were placed on a sheet of parafilm and held on ice 30 cm from a 15-W germicidal ultraviolet lamp for various times. They were then added to 15 µl of the mixture described in Fig. 1, and incubated at 30 °C. Double-stranded RNA was present at a concentration of 20 µg ml⁻¹ to avoid inhibition of protein synthesis by low levels of endogenous double-stranded RNA present in the core preparations (see ref. 22). After 1 h of incubation, a further 10 µl of translation mixture was added, and the incubation continued for another 1 h. Samples (5 µl) were analysed on a 15% SDS-polyacrylamide gel. A fluorogram of this gel is shown. The molecular weights (× 10⁻³) indicated in the margin were derived by comparison with a set of ¹⁴C-iodoacetate-labelled marker proteins run in parallel with the experimental samples. Arrow indicates a background band which is labelled even in the absence of cores. The sample in the left-hand track contained no cores; others contained cores irradiated for the number of minutes indicated.

about 1 h. About 30–40 discrete polypeptides are made, many of which comigrate with authentic early vaccinia proteins on two-dimensional polyacrylamide gels of the O'Farrell type¹⁹ (data not shown). This protein synthesis is completely prevented by 7 µg ml⁻¹ actinomycin D, whereas the translation of globin or preformed vaccinia mRNA is unaffected by the drug. Protein synthesis in the coupled system is therefore dependent on the transcription of vaccinia DNA. Coupling RNA and protein synthesis in this way avoids the need for an intermediate purification of the RNA, thus eliminating errors due to unequal recovery of different messages. The direct study of

Fig. 3 Rate of ultraviolet light inactivation of synthesis of vaccinia proteins. *a*, Relative amount of radioactivity in five representative polypeptides plotted against the time of exposure of the cores to ultraviolet irradiation. This was determined by densitometry of appropriately exposed fluorograms such as that shown in Fig. 2, and is expressed as a percentage of the radioactivity obtained with non-irradiated cores. Molecular weights of these proteins: \square , 116,000; \triangle , 63,000; \bullet , 36,500; \square , 29,000; ∇ , 17,000. *b*, Plot of 17 first-order rate constants, determined from plots such as those in *a*, against the molecular weights of the corresponding proteins. Solid symbols refer to the five proteins shown in *a*. These figures were compiled from data obtained in two independent experiments.

individual mRNAs is made difficult by their poor resolution on gradients and gels, due to a combination of their similar sizes and their heterogeneous poly(A) tails.

Vaccinia cores were exposed to a germicidal ultraviolet lamp for periods ranging from 5 s to 8 min, and then added to the cell-free system. After incubation for 1 h, fresh lysate was added, and incubation continued for a further 1 h. In these conditions the mRNA produced does not saturate the system, so that competition between mRNAs is avoided. The protein products were analysed on SDS-polyacrylamide gels, and their synthesis measured either by densitometry of appropriately exposed fluorograms²⁰, or by direct counting of excised protein bands. The results are shown in Figs 2 and 3. The decay of the synthesis of each protein obeyed single-hit kinetics, but the rate constant varied according to the protein (Fig. 3a). Fig. 3b plots the rate of inactivation of the synthesis of the 17 most prominent proteins against their molecular weights, which were estimated relative to a set of marker proteins run on the same gel. Thirteen of these bands, including the largest at 116,000, comigrate on SDS gels with proteins labelled in infected cells; at least four correspond to major polypeptides which comigrate on two-dimensional gels with authentic vaccinia-induced proteins (H. R. B. Pelham, unpublished). The other bands are probably not the result of premature termination of translation; analysis of partial digests of the products after labelling with formyl-³⁵S-methionine indicates that they do not share common N termini (H. R. B. Pelham, unpublished).

There is a linear relationship between the molecular weight of the proteins made *in vitro* and the rate of ultraviolet inactivation of their synthesis (Fig. 3b), which argues strongly against tandem polycistronic transcription of their mRNAs. If such transcription were happening, there would be proteins whose synthesis was much more sensitive to ultraviolet light than would be expected from their size. This experiment does not exclude the possibility that the mRNAs are derived from longer monocistronic precursors whose size is directly proportional to the size of the coding regions. This seems intrinsically unlikely, and we have failed to detect any large core-associated precursors to mRNA by pulse-labelling experiments. Such experiments would not, however, detect precursors which were cleaved while still nascent. An argument in favour of the idea that the mRNAs synthesised by vaccinia cores represent primary transcripts has been made by Ball and White¹⁵. Unlike VSV,

vaccinia cores seem to be unable to add caps to the ends of RNA molecules generated by cleavage. Since, as I shall show elsewhere, vaccinia mRNA has a strong requirement for capped 5' ends for its translation, it is difficult to accept that messages produced by a cleavage pathway could be active.

These arguments and the data presented above strongly suggest that the major mRNA species produced by vaccinia cores are uncleaved transcripts of single cistrons, modified by the addition of poly(A) at the 3' end and a cap at the 5' end.

The coupled system used in this work is the first example of a eukaryotic cell-free system in which efficient RNA and protein synthesis are directed by a DNA template. It thus offers an *in vitro* analogue of infected cells, and should be useful for studying further aspects of gene expression in vaccinia virus.

I thank Jane Sykes for supplying the vaccinia cores, and Tim Hunt for help in preparing the manuscript. I am the holder of an MRC studentship, and the work was supported by a grant from the MRC to Dr R. J. Jackson.

Foreign DNA of bacterial plasmid origin is transcribed in crown gall tumours

Agrobacterium tumefaciens incites cancerous growths in dicotyledonous plants called crown gall tumours. Large plasmids in oncogenic *Agrobacterium* strains¹ carry genetic information which is essential for tumour induction^{2,3}. We recently reported that axenic crown gall tumour tissue contains multiple copies of a small part of the oncogenic (Ti) plasmid of the inciting bacterial strain⁴. The mechanism of induction of crown gall tumours thus seems to resemble that of some virally induced animal tumours: the eukaryotic cell is transformed by addition of new genetic information which is stably maintained through subsequent cell divisions⁵⁻⁷. The means by which foreign DNA brings about the tumorous growth pattern of crown gall cells is unknown. The first step in elucidating its mode of action is reported here: we have detected RNA tran-

were resolved into 21 bands by Agarose gel electrophoresis⁴. Plasmid DNA fragments were alkali-denatured in the gel, neutralised and transferred directly to a sheet of cellulose nitrate^{8,9}. The pattern of bands obtained by electrophoresis was thereby reproduced on the sheet, which was then cut into longitudinal strips for separate hybridisation experiments.

Strips were incubated with labelled RNA isolated from clone E9 of a tobacco tumour incited by strain B6-806, and from normal tobacco callus tissue. In addition, a strip was incubated with ³²P-cRNA synthesised⁹ from the whole Ti plasmid genome by *Escherichia coli* RNA polymerase. Autoradiograms of the hybridised filter strips are shown in Fig. 1 together with a photograph of the bands of DNA in the gel used to prepare the cellulose nitrate transfers. Labelled tumour RNA hybridised to a single band of the *Sma* I digest, identified as band 3 by comparison with the photograph of the gel and the autoradiogram of the cRNA hybrid strip. We have shown that this tumour clone contains about 18 copies, per diploid tobacco cell DNA equiv-

Fig. 1 Hybridisation of labelled E9 tumour and control RNAs to strips bearing *Sma* I digest bands. Tumour and normal callus tissues, tested for sterility at the time of labelling, were incubated in Petri dishes with approximately 1 mCi ³²P (neutralised) per g of tissue for 4 h. RNA was isolated by hot phenol extraction, DEAE-cellulose chromatography, DNase digestion and gel filtration on Sephadex G-75 (ref. 12). Specific activities of RNAs were 127,000 c.p.m. per μ g (tumour) and 34,000 c.p.m. per μ g (normal callus). For cRNA synthesis ³²P-UTP (ICN, 75 Ci mMol⁻¹) was used as labelled precursor, and plasmid from strain A277 served as template. Pure virulence plasmid of *A. tumefaciens* B6-806 was isolated from exconjugant strain A277 and digested with *Sma* I as described previously⁴. After electrophoretic separation in 0.5% Agarose, the bands were stained and photographed⁴ before denaturation and transfer of bands to cellulose nitrate sheets (Schleicher and Schuell, B6 membrane). Strips were soaked in Denhardt's¹³ pre-incubation mixture and baked at 55 °C overnight before use. Hybridisation was carried out with 5×10^6 c.p.m. ml⁻¹ labelled RNA and 200 μ g of unlabelled carrier RNA in 0.3 M NaCl, 0.03 M trisodium citrate ($2 \times$ SSC) at 67 °C for 20 h. Filter strips were wetted with $2 \times$ SSC before addition of labelled RNA. Unlabelled carrier RNA was isolated from strain A114, an avirulent plasmidless derivative of strain C58 (ref. 3). After incubation, strips were washed ($2 \times$ SSC 67 °C), treated with RNase (20 μ g ml⁻¹, 1 h, 22 °C), rinsed, dried and autoradiographed for 36 h to 2 weeks. All radioactive label was entirely acid precipitable at the end of the incubation. Autoradiograms of filter strips hybridised with E9 tumour RNA, normal callus RNA and cRNA are presented beside a photograph of the original gel, adjusted to the same scale photographically.

scripts of the foreign genetic information in the tumour cell.

³²P-pulse-labelled RNA was isolated from tumour and normal tobacco callus tissues as described in Fig. 1. To test these RNA preparations for the presence of RNA transcripts of Ti plasmid DNA, we used a filter hybridisation technique developed by Southern⁸. Ti plasmid DNA from the inciting bacterial strain was first cleaved into 25 specific fragments with the restriction endonuclease *Sma* I. These

alent, of part of *Sma* I digest band 3, by direct DNA-DNA hybridisation technique⁴. Our findings show that at least a part of this genetic information is transcribed in the tumour cell. Recent studies have shown that this tumour clone also contains a part of *Sma* I digest band 10 (ref. 10). In three separate experiments using different lots of pulse-labelled tumour RNA from this clone, no hybridisation was noted to band 10 or any other *Sma* I digest bands; only band 3 transcripts were detected. Normal

Fig. 2 Hybridisation of labelled E9 tumour RNA to strips bearing plasmid *Eco* RI digest bands. The labelled E9 tumour RNA (5×10^6 c.p.m. ml⁻¹) was incubated for 16 h (67 °C, $2 \times$ SSC) with cellulose nitrate strips bearing *A. tumefaciens* strain A277 plasmid *Eco* RI/(Miles) digest bands (prepared as for Fig. 1). A line drawing of the bands seen in a photograph of the gel is shown below the autoradiogram of the hybridised strip. Hybridisation is assigned tentatively to bands 12, and 21, 22. (Close neighbouring bands make this assignment equivocal.) The 6,7 doublet has been proposed to bear virulence functions¹¹.

Fig. 3 Hybridisation of labelled E1 tumour RNA to strips bearing plasmid *Hind*III digest bands. Labelled E1 tumour RNA (3 h pulse, 46,000 c.p.m. per μ g) was isolated as described in Fig. 1. Cellulose nitrate strips bearing *Hind*III (New England Biolabs) digest bands of strain A277 plasmid were prepared, and labelled RNA (4×10^6 c.p.m. ml^{-1}) was hybridised with the strips for 16 h ($2 \times \text{SSC}$, 67°C), washed and RNase treated as for Fig. 1. A line drawing of the bands, prepared from a photograph of the gel, is shown below the autoradiogram of the strip. Labelled E1 tumour RNA hybridisation is assigned to *Hind*III bands 1 and 5.

callus tissue RNA was never observed to bind to any fragment of the plasmid, even after fivefold longer exposure of the autoradiograms.

Further experiments were carried out using ^{32}P -RNA form clone E9 and filter strips carrying bands of *Eco* RI digest of the Ti plasmid. The numerous fragments in this digest (Fig. 2) are not well separated by electrophoresis; thus the identification of bands is imprecise. Tumour RNA hybridised well to a band in the region of band 12, and weakly to a band in the region of the band 21,22 doublet. The latter band, while clearly visible in the autoradiogram, is too faint for photographic reproduction in Fig. 2. Doublet *Eco* RI digest band 6,7 has been proposed to be important in tumour initiation because it seems to be common to distantly related virulence plasmids¹¹. We detected no transcript of this band in this tumour clone. Labelled RNA from normal callus tissue did not bind to any bands on filter strips bearing *Eco* RI digest bands (data not shown).

Labelled RNA from tumour clone E1, a single-cell isolate from the same tumour as E9, hybridised to *Sma* I digest band 3 (data not shown). When this RNA was hybridised to cellulose nitrate strips bearing *Hind*III digest fragments of the Ti plasmid, bands 1 and 5 gave positive results (Fig. 3). Thus these singlet bands appear to contain the same genetic information as the relevant member of the *Sma* I band 3 doublet, which we have identified as band 3b as described elsewhere⁴.

Results presented here show that pulse-labelled crown gall tumour RNA can be used to identify DNA fragments, within any restriction endonuclease digest, which contain Ti plasmid DNA base sequences transferred to the tumour cell. Although not all the foreign DNA is transcribed at detectable levels in the tumour, at least part of the transferred DNA can be detected in this manner. DNA fragments shown to be contiguous by conventional mapping procedures may then be tested for homology with tumour DNA.

Our data confirm, by an independent experimental approach, the presence of a specific part of the Ti plasmid in crown gall tumour cells. Also, these data constitute the first convincing evidence that DNA of bacterial origin is transcribed in demonstrably axenic plant tissue. The possibility must be considered, however, that the transcribed genes in question may ultimately be of plant origin, having been picked up by the *A. tumefaciens* Ti plasmid in the course of its evolution. Should this be the case, one might expect these genes to remain untranscribed in the bacterium. Experiments are in progress to determine whether this is in fact the case. If the same RNA transcripts prove to be present in both the bacterial and the crown gall tumour cell, an unsuspected degree of compatibility between transcriptional processes in eukaryotic and prokaryotic systems will be revealed.

This research was supported by grant CA13015 from the National Cancer Institute and grant number NP194 from the American Cancer Society. We thank Mr Chips Armstrong for prints of autoradiograms. We thank Dr

Daniela Sciaky for useful discussions and Dr Benjamin D. Hall for a gift of *E. coli* RNA polymerase.

Decreased initiation factor activity in mouse L cells treated with interferon

INHIBITION of virus-directed protein synthesising events in extracts of cells treated with interferon has been reported¹⁻³. Inhibition of translation of viral mRNAs has been associated with a protein bound to ribosomes of cells treated with interferon^{4,5}. This inhibition may involve the initiation or elongation steps in protein synthesis^{6,7}. Recently, initiation factors for protein synthesis have been isolated from a variety of eukaryotic cells, and it has been established that the initiation factors interact with non-formylated methionyl initiator RNA (Met-tRNA_i) and GTP to form a ternary complex^{8,9}. The experiments presented here show that the activity of initiation factor(s) to form a ternary complex may be impaired or altered in mouse L cells treated with homologous interferon. In preliminary experiments with the initiation factor preparation it was confirmed that the formation of a ternary complex (Met-tRNA_i-eIF-GTP) required GTP for maximal formation (within 2 min at 37°C) and the amount of complex formed was directly proportional to the concentration of initiation factor (Fig. 1). ATP did not substitute for GTP and Mg^{2+} inhibited its formation (data not shown).

When mouse L cells were exposed to (homologous) mouse interferon (100 U ml^{-1}) for 24 h, the initiation factor activity was inhibited about 60%, as compared with untreated controls (Fig. 2). A similar decrease in the activity followed a 6-h treatment of the cells with the same unitage of partially purified mouse interferon (specific activity: 10^7 U mg^{-1} protein). As little as 20 U ml^{-1} mouse interferon resulted in significant inhibition (about 18%). It should be noted that the initiation factor activity of interferon-treated cells reached a plateau at a concentration of $90 \mu\text{g}$ protein and the activity gradually decreased at concentrations higher than

Fig. 1 GTP requirement for formation of ternary complex by initiation factor from mouse L cells. Initiation factor preparation was extracted from exponentially growing mouse L cells treated or untreated with interferon (about 2×10^9 cells). The cells were homogenised in 25 ml 10 mM Tris-HCl buffer (pH 7.5) containing 10 mM KCl, 5 mM $MgCl_2$ and 2 mM dithiothreitol, and centrifuged for 20 min at 12,000 r.p.m. Ribosomes from this supernatant were prepared according to the method of Levin *et al.*⁸. The ribosomes were gently stirred in 8 ml 10 mM Tris-HCl (pH 7.5) containing 0.25 M sucrose, 1 mM EDTA, 2 mM dithiothreitol and 0.5 M KCl for 60 min at 4 °C. After centrifugation at 105,000g for 3 h, the supernatant was precipitated with solid ammonium sulphate (0.361 g ml⁻¹), then re-dissolved in 1.0 ml 10 mM Tris-HCl (pH 7.5), containing 0.1 M KCl, 2 mM dithiothreitol and 5% glycerol, and dialysed against 300 ml of the same buffer for 4 h. All procedures were carried out at 0–4 °C. Rat liver Met-tRNA_f was purified from rat liver using DEAE-cellulose¹⁰ and BD-cellulose¹¹ chromatography successively and then charged with ³⁵S-methionine (22.3 Ci mmol⁻¹) using Met-tRNA synthetase purified from *Escherichia coli*⁸. Initiation factor activity was assayed as follows: each 0.1 ml of the reaction mixture contained 40 mM Tris-HCl (pH 7.5), 5 mM dithiothreitol, 0.1 M KCl, 50 pmol ³⁵S-Met-tRNA_f (3,500 c.p.m. pmol⁻¹) and the amount of initiation factor indicated in the text. The solution was mixed on a vortex mixer before and after the addition of initiation factor, then incubated at 37 °C for 5 min in the presence or absence of 5 mM GTP. The complex formation (³⁵S-Met-tRNA_f.eIF.GTP) was determined by dilution with 1.5 ml 20 mM Tris-HCl (pH 7.5), containing 50 mM KCl, 10 mM $MgCl_2$ and 1 mM DL-methionine and passage through a nitrocellulose membrane filter (Millipore, type HA). The filter was washed with four additional 2.0-ml aliquots of buffer. After drying, the radioactivity associated with the filter was measured. Protein was determined by the methods of Bücher¹² and Groves *et al.*¹³. The initiation factor from the ribosomes of mouse L cells was prepared and assayed in the presence (○) or absence (●) of GTP. The initiation factor preparation contains initiation factor(s) and ribosomal components which elute from ribosomes and purify in the present conditions.

130 mg (Fig. 2). No effect was detected when mouse L cells were treated with 100 U ml⁻¹ heterologous human leukocyte interferon for 24 h. The reduction in initiation factor activity induced by interferon was prevented by inhibition of cellular RNA synthesis with actinomycin D (98% inhibition of cellular RNA synthesis) or by inhibition of cellular protein synthesis with cycloheximide (93% inhibition of cellular protein synthesis) (Fig. 3a and b). Furthermore, the activity of initiation factor was not inhibited by mouse

interferon added directly to the assay reaction mixture. This finding is not consistent with the proposal that interferon itself is a modified initiation factor¹⁴.

Evidence indicating that the interferon in the preparation was responsible for the altered initiation factor activity comes from the above findings that: (a) partially purified interferon (which originated from a different mouse cell source) had the same effect as crude interferon; (b) heterologous human interferon at levels which did not induce antiviral activity in mouse cells had no effect on the activity of initiation factor; (c) inhibition of cellular RNA synthesis by actinomycin D prevents both the antiviral activity and the alteration of initiation factor activity by interferon; (d) inhibition of protein synthesis by cycloheximide blocks both the antiviral activity and the change of initiation factor activity; and (e) interferon which does not directly inhibit virus, when added directly to the initiation factor assay system did not inhibit the activity (data not shown). Taken together, these findings show that the initiation factor activity from interferon treated mouse L cells was consistently and significantly reduced when compared with the initiation factor activity obtained from control cells. These characteristics coincide with those which are considered to be specific for interferon¹⁵.

A preliminary attempt to compare the physical properties of the initiation factor extracted from control and from interferon-treated cells was carried out by studying their heat stabilities. Initiation factor from cells treated and untreated with interferon were incubated at 50 °C for the times indicated in Fig. 4, and then

Fig. 2 Comparison of initiation factor activity from mouse L cells treated and untreated with interferon. Exponentially growing monolayers of mouse L cells were treated with 100 U ml⁻¹ of either mouse interferon (Bionetics Corporation) or human leukocyte interferon for the indicated periods in the presence of 2% foetal calf thymus. After treatment of the cells with interferon, they were collected and washed with 10 mM Tris-HCl (pH 7.5) containing 10 mM KCl, 5 mM $MgCl_2$ and 2 mM dithiothreitol. The initiation factors from the cells were prepared and assayed as described in Fig. 1. Initiation factor activity of the cells exposed to mouse interferon (●), human interferon (Δ), or partially purified mouse interferon 100 U ml⁻¹ for 6 h (■), ○, untreated cells. The difference between the average values of initiation factor activity from interferon-treated and control cells observed in eight different experiments are statistically significant ($P < 0.001$ using Student's *t* test).

assayed for residual activity. With a little as 15 min of heating, the initiation factor from interferon treated cells showed greater stability than initiation factor from untreated cells or from cells treated with both actinomycin D and interferon. This finding suggests that interferon either induces an alteration of the normal initiation factor or it induces an inhibitory material which combines with and alters the normal factor. The latter possibility is consistent with the finding that increasing concentration of initiation factor from interferon treated cells results in increasing inhibition of activity (Fig. 2).

Several previous reports have indicated that the translation of added viral mRNAs is impaired in a mixture of extracts from interferon-treated cells more than that of cellular mRNAs³⁻⁵. This inhibitory effect is thought to be mediated by the induction with interferon of a new, cellular antiviral protein which may act by one or more mechanisms: impairment of the binding of viral mRNAs to ribosomes¹⁶; alteration of the methylation of mRNAs¹⁷; restriction of the availability of a minor species of tRNA required for translation^{18,19}; and induction of a nuclease which impairs translation²⁰. The present finding that the initiation factor from interferon-treated cells has diminished activity to form a ternary complex narrows the possible mechanisms in favour of an effect on initiation and will be used in our further studies to help define the basis of selective inhibition of viral translation in interferon-treated cells. Note that the effect of interferon on activity of initiation factor is the earliest event in the sequence of protein synthesis which has been shown to be inhibited by interferon. Other important questions which merit further study include: (a) Can the impairment of initiation factor activity be observed in intact cells treated with interferon? (b) Is the degree of inhibition of initiation factor activity in cells treated with interferon sufficient to account for the reported impairment of the functions of resting, rapidly metabolising and tumour cells? (c) Can the decreased initiation factor activity be overcome by formylated initiator tRNA as has been described for encephalomyocarditis virus polypeptide chains⁹? The latter mechanism may provide a

Fig. 3 Effect of actinomycin D and cycloheximide on the impairment of initiation factor activity by interferon. *a*, Activity of initiation factor preparation from L cells exposed to partially purified mouse interferon 100 U ml⁻¹ for 6 h (●), pretreated with actinomycin D 2 μg ml⁻¹ for 60 min, or incubated for 6 h in the absence (×) or presence (Δ) of interferon. Untreated cells (○). *b*, Activity of initiation factor from L cells exposed to partially purified mouse interferon 100 U ml⁻¹ for 6 h (●), pretreated with cycloheximide 100 μg ml⁻¹ for 30 min, or incubated for 6 h in the presence of interferon and cycloheximide (Δ) or in the presence of cycloheximide (×). Untreated cells (○).

Fig. 4 Temperature sensitivity of initiation factor activity from cells treated and untreated with interferon. Each initiation factor preparation (0.5 mg protein) was incubated at 50 °C for the indicated periods. After heating the initiation factor preparation was tested for ability to form a ternary complex. Initiation factor activities from cells treated for 6 h with partially purified mouse interferon 100 U ml⁻¹ (●), and from interferon-treated cells after treatment with actinomycin D 2 μg ml⁻¹ for 60 min (Δ), ○. Untreated cells.

discrimination between viral mRNAs and host mRNAs at initiation level, because the ternary complex formation in eukaryotic system requires Met-tRNA_i as described previously^{8,9}.

Nuclear theory

D. F. Jackson

A Unified Theory of the Nucleus. By K. Wildermuth and Y. C. Tang. Pp. x+389. (Academic London and New York, 1977) \$38.50; £27.35.

In nuclear theory the essential problem is to reduce the description of a many-particle system to manageable proportions without the introduction of too many arbitrary assumptions and with the possibility of estimating the effects of approximations made. In the unified theory of nuclear reactions, particularly associated with the name of Feshbach, projection operators are used to reduce the true many-particle Hamiltonian to effective Hamiltonians, which belong to subspaces of the total Hilbert space but contain the correct asymptotic boundary conditions for the final states. In contrast, Wildermuth and Tang propose a theory in which the total wavefunction for the many-particle system is represented as a sum of non-orthogonal terms each corresponding to a final system with the correct boundary conditions. Thus, the subspaces of the total Hilbert space are defined through the wavefunction and, it is argued, this provides the correct asymptotic behaviour for the initial state and all final states.

The authors apply their approach to a variety of bound-state and reaction problems. The terms of the wavefunction each correspond to a possible cluster structure of the many-particle system, although, as the authors repeatedly stress, it is inappropriate to take these cluster structures too literally because of the effect of the anti-symmetrisation operator which exchanges particles between the clusters. Among the problems discussed are the construction of bound-state wavefunctions and the evaluation of charge density distributions, ground-state energies and transition probabilities, the scattering of light systems at low and medium energies, resonance reactions, the microscopic formulation of optical potentials, and fission.

This book covers a very wide range of nuclear physics and contains some penetrating observations about aspects of the theory. It is, however, a rather frustrating book to read. So many topics are started and reach a premature conclusion with a rather trivial

example based on a very light system such as ^4Be or ^4Li . There is a useful discussion of the generator coordinate technique but recent developments in the resonating group method and the orthogonality condition model are ignored. The discussion of optical potentials for composite particles completely ignores extensive work done with folding models. The most serious weakness of the approach is that, although great emphasis is laid on the

need for correct asymptotic behaviour of wavefunctions, all the examples fall back on oscillator functions which are notoriously incorrect at large separation distances. Until the practical application of the theory can be extended to yield the correct asymptotic behaviour the formal theory is unlikely to lead to major advance. □

Cancer chemotherapy

Biosynthetic Products for Cancer Chemotherapy Vol. 1. By G. R. Pettit. Pp. xii+215. (Plenum: New York and London, 1977.) \$23.40

THE author states that his main aim is "to provide a current overall view of the cancer problem and the development of cancer chemotherapeutic drugs of biosynthetic origin". If you want a reasonably detailed summary of the chemical and biological properties of the kinds of cytotoxic products which have been isolated from plants, micro-organisms, marine organisms, reptiles and other sources, then this book, from p47 on, may supply your needs.

It is less easy to know for whom the whole book was written. The first chapter (Introduction and Perspective) is the longest (46 pages); in it, the author discusses the nature, causation, and treatment of cancer with special emphasis on the role of the National Cancer Institute. Such a survey seems out of place and belies the title of the book. Dr Pettit could undoubtedly write a useful review or two on different aspects of cancer chemotherapy, but not, as here, by trying to cram a quart into an inappropriate pint pot.

In his introductory chapter, the author refers to the ten or so malignant conditions particularly amenable to drug treatment, without making it clear that these are relatively rare cancers. Their control is a commendable achievement, but is only a scratch on the surface of the cancer problem.

On the credit side, the author and publishers are to be complimented on the clear and numerous structural formulae. They occupy, however, all

of 80 pages, leaving only about 75 pages of text for the natural products section of the book. Dr Pettit has succeeded in compressing a large amount of information into these pages, and the comprehensive tabular survey which volume 2 will provide, promises to be a useful supplement.

The author's enthusiasm often comes through, insufficiently tempered, perhaps, by an acknowledgement of the limitations of cancer chemotherapy in man at the present time. He clearly feels that much more money could usefully be spent on the exploration of natural products as potential anti-tumour agents. He may be right, but some of his statements would not find universal acceptance. Take, for example, the dogmatic comment on p175: "Given sufficient financial support and time, the lower animals will prove to be a particularly good source of unusual and valuable drugs for cancer chemotherapy". Again, the author seems to imply (p58) that, with sufficient knowledge, one could design a single substance effective against human cancer in its various forms, a view now held by few.

Such criticism does not invalidate the work as a handy reference book on a range of naturally occurring cytotoxic compounds, although—if the reviewer may now be dogmatic—the very great majority of these products will never become established as clinically useful drugs. One must therefore not take the title of the book too literally.

J. A. Stock

J. A. Stock is Senior Lecturer in Chemistry at the Chester Beatty Institute of Cancer Research, London, UK.

Inorganic azides

Energetic Materials Vol. 1: Physics and Chemistry of the Inorganic Azides Pp. 503. \$59.40. Vol. 2. Technology of the Inorganic Azides. Pp. 296. \$90. Edited by H. D. Fair and R. F. Walker (Plenum: New York and London, 1977).

THESE volumes review recent research and development work in the physics, chemistry, and technology of the inorganic azides. Summarising fundamental advances over the past two decades, emphasis is placed on investigations supported by the United States Army through its Office of the Chief of Research and Development and its Materiel Command. The contributing authors are, for the most part, members of the Energetic Materials Division (formerly Picatinny Arsenal), Armament Research and Development Command, New Jersey.

The wide variation in crystal bonding characteristics and stability of the inorganic azides present problems of unique interest in solid state physics and chemistry. In the reactive state, the inorganic azides exhibit a remarkable range of reactivities from low order decomposition, deflagration, to high order detonation. These properties have led to the commercial development of azides in a wide field, including particularly gas-generating devices and explosives, as well as photographic emulsions.

One of the central and fundamental problems in the study of azides lies in the development of valid equations of state applicable to the explosive decomposition of these materials. This requires the elucidation of interatomic forces from data on vibrational levels obtained from crystal spectra. Considerable success along these lines obtained with the solid alkali metal halides, using dynamic models, has very recently been applied to the inorganic azides, using laser Raman and thermal neutron spectroscopy. The results of these studies have contributed greatly to our understanding of lattice and phase transition dynamics in the crystalline metal azides. Another important area concerns the calculation of activation energies of decomposition, and the correlation of these with ground and excited energy levels in the azide crystal.

These major aspects are reviewed comprehensively in Volume 1, which deals with azides across the whole range of the Periodic Table, with particular reference to azide crystals and crystal structure; molecular vibrations in lattices; electronic structure of the

solid state, and all aspects of decomposition, initiation and propagation in solid metal azides.

Volume 2 is devoted to the technology of those metal azides used in detonators, and as such is largely concerned with lead and silver azides. The aspects covered comprise manufacturing techniques and process control; analysis of azides, handling and safety; sensitiveness and the roles of azides in detonating trains. The section on electrostatic sensitivity and dielectric properties of lead azide and other primary explosives is of great current interest. The final section on the initiation of detonating trains by azides, also merits comment. In these situations lead azide functions commonly both as

acceptor and as donor. These two processes together determine the pulse time and shape of the impulse integral on which the detonation threshold of the secondary charge depends. Recent high precision data are presented on these phenomena.

In conclusion, these volumes offer an extremely comprehensive, well-documented review of the most significant aspects of the science and technology of the inorganic azides. This work will be of inestimable value, particularly to those concerned with the development of military and commercial explosives. **J. H. Turnbull**

J. H. Turnbull is Professor and Head of the Chemistry Branch, Royal Military College of Science, Shrivenham, UK.

Aerosol research and technology

Smoke, Dust and Haze: Fundamentals of Aerosol Behaviour By S. K. Friedlander. Pp. xvii+317. (Wiley: New York and London, 1977) \$19.50; £11.35.

AEROSOL research and technology is, like most modern fields of interest, complex and interdisciplinary. Whereas transport, deposition, collision and coagulation are merely governed by physical laws, the formation of particles is largely a chemical problem. Meteorological processes such as rain-out, wash-out, and boundary layer physics are involved as well as engineering aspects for the design of sampling and measuring devices.

The available literature is specialised on certain aspects of the complex field, and there is a strong need for a comprehensive presentation especially for those who want to get into this field. Friedlander's book is likely to close a great deal of this gap. Written as a classroom text for graduate students in environmental engineering it mainly covers the physical and engineering aspects of aerosol behaviour.

The first third of the book is devoted to particle transport and deposition. Excellent fundamentals of problems, such as diffusion and deposition for different flow parameters, filter efficiencies, electrical precipitation, inertial and turbulent deposition, are given.

The second third deals with fundamentals of particle generation and growth. Collision and coagulation processes, thermodynamic processes, such as condensation, formation and stability of droplets and clusters, and a brief outline on gas-to-particle conversions, are presented.

In the last part, a general dynamic equation for the continuous distribution function is set up taking into account all processes of particle formation, growth, diffusion, coagulation, convection, and sedimentation discussed before. Special cases, in particular the dynamics of turbulent stack plumes, are discussed and compared with observational data. The techniques for setting up predictive models for air quality-emission source relationship are briefly described.

A short chapter on optical properties is confined to light scattering and visibility. For the complete problem of radiative transfer the reader is referred to the specialist literature. In another short chapter on experimental methods, descriptions of sampling, filtration, particle counters, the cascade impactor, devices for chemical analysis, and aerosol generators, are given.

The book is clearly written and beautifully made. At the end of every chapter carefully selected examples and problems provide excellent applications of the fundamentals treated. Friedlander concentrates mainly on the physical aspects of aerosol behaviour. Important chemical processes such as gas-to-particle conversion through heterogeneous reactions and meteorological aspects of particle transport and precipitation are only briefly outlined for completeness. It would be highly desirable to see equally well produced books covering the chemical and meteorological aspects being published.

This book is more than a textbook for graduate students in environmental engineering. It should be on the bookshelf of every scientist and engineer directly or indirectly involved in aerosol research and technology. **P. Fabian**

P. Fabian is Head of the Department of Atmospheric Minor Constituents, Max-Planck-Institut für Aeronomie, Katlenburg-Lindau, West Germany.

Molecular weight determination

Molar Mass Measurements in Polymer Science. By N. C. Billingham. Pp.254. (Kogan Page: London, 1977.) £13.50.

DISCUSSION of the theories underlying molecular weight determinations is almost an incidental part of most textbooks of polymer science. In contrast, practical aspects of the various techniques are most commonly discussed in the instruction manuals issued by appropriate manufacturers. The author of this book has made a highly successful attempt to combine the two sources of information into a most useful and reasonably concise reference text.

As the title indicates, the book is written with a fairly rigid adherence to the SI system of units; molar mass, a fundamental unit with dimensions, being preferred to the more generally used, dimensionless quantity, molecular weight.

In the early part of the book the various molar mass averages, and their relationships, are discussed as a preliminary to a most enlightening survey of the nature and behaviour of polymer molecules in solution. Membrane

osmometry, vapour pressure, light scattering, ultracentrifuge, viscosity, and gel permeation chromatography techniques are fully described in later chapters and, for each, there is a discussion of both underlying theory and practical laboratory procedures. Different types of instruments supplied by various manufacturers are individually described and compared, and full details of equipment suppliers and a list of suitable solvents for most common polymers are included as appendices. There is also a very short discussion of chemical methods for assay of endgroups in polymers.

In total, the contents of this book are rather similar to those of two edited volumes (*Polymer Molecular Weights*, ed. P. E. Slade, Jr, recently published) and indicate the requirement for a convenient reference text of this kind. The present single volume, however, has the advantages of both lower price and a more coordinated treatment of the subject. It will be valuable to anyone interested in polymer characterisation and especially to research workers who may be abruptly faced with the problems of molecular weight determination.

A. Ledwith

A. Ledwith is Professor of Chemistry at the University of Liverpool, UK.

Liquid-state chemistry

Introduction to Liquid State Chemistry. By Y. Marcus. Pp. viii+357. (Wiley-Interscience: London and New York, 1977.) £12.50; \$24.00.

LIQUID-STATE PHYSICS is a flourishing branch of science which has been reviewed recently in several good books. The liquids discussed were those whose structure is the most easily determined, and whose properties provide the most direct test of physical theories; argon is the archetype. Professor Marcus has a different aim—to give an account of the equilibrium properties and structure of those liquids that are of more concern to the chemist. "Crude petroleum, sea water, aqueous acetone and molten cryolite" are his examples.

Before tackling his main subject, he rightly supposes that his reader will need first to know something of the physics of simple liquids and their mixtures, and so the first half of his book is essentially liquid-state physics. Unfortunately, 160 pages is too small a space for this to be anything but a string of theories, models, approximations, and references. Those familiar with the field might wish that he had been more critical in his choice of material; those who are not, will probably gain little but a list of references and useful tables, since the text is not only too condensed but abounds with errors and examples of misplaced emphasis.

The second half of the book covers his main interest; there are chapters on mixtures of molecular liquids, solutions of electrolytes, molten salt mixtures, and mixtures of liquid metals. Here, the level of rigour of the physics is necessarily lower than in the earlier chapters; often a well chosen correlation of physical properties is more valuable than a neat trick with the grand partition function. Chemists who work with liquids will welcome the last four chapters, with their extensive tables and full references.

The units of the book are said to SI, but this system implies not only the use of metres, kilogrammes, seconds, and so on, but also the use of the rationalised electromagnetic system. Unfortunately, the author has married the sizes of the units of the SI with equations of the unrationalised electrostatic system, so that we have, for example, a polarisability in $\text{m}^3 \text{mol}^{-1}$. This combination will probably confuse students reared on the *Système International*, and not only on its units.

J. S. Rowlinson is Professor of Chemistry at the University of Oxford, UK.

Advances in Invertebrate Reproduction

Volume I

Edited by K. G. Adiyodi & Rita G. Adiyodi
1977; xii+514pp.; art paper; hard bound; £23/\$40
(inclusive of postage)

Proceedings of the First Symposium of the International Society for Invertebrate Reproduction, Calicut, September 10-12, 1975. Updated and revised. The 39 original contributions and overviews by leading authorities in the field cover several fascinating aspects of sexuality, reproduction and behaviour of a wide range of invertebrates. Some of the comparative data given on vertebrates add to the usefulness of this volume. Profusely illustrated and complete with author, subject and species indexes.

Precambrian formations

Precambrian of the Northern Hemisphere. By L. J. Salop. Pp.ix+378. (Elsevier Scientific: Amsterdam, New York and Oxford, 1977.) Dfl.145; \$59.25.

THIS book provides an "inter-regional correlation of Precambrian formations", the subdivisions of which are based on the "natural stages in the earth's evolution". Essentially the book is a correlated list of the Precambrian formations of the northern hemisphere.

Three introductory chapters are largely concerned with methods and principles of correlation and subdivision, and the two final chapters review briefly the major features of geological evolution during the Precambrian (tectonic models and plate tectonics are avoided). The six main chapters list the principal rock groups in Salop's six subdivisions, as follows: (1) The Archaean era includes all rocks formed more than 3500 Myr ago (largely gneisses and granulites). (2) The Paleoprotozoic ("Protozoic" is Salop's new term) (3500–2600 Myr) which concerns the well-known greenstone belts. (3) The Mesoprotozoic (2600–1900 Myr) including geosynclines like Krivoi Rog, the Huronian and the Labrador Trough. (4) The Neoprotozoic (1900–1000 Myr) which deals with clastics and red beds in platforms and aulacogens (for example, Gardar and Keweenaw) and the gabbro-anorthosite-rapakivi granite-alkali syenite complexes. (5) The Epi-protozoic (1000–650 Myr) including platform and miogeosynclinal, mostly terrigenous (especially red bed) facies and the prominent tillites (for example, lower Dalradian, upper Briovarian). (6) The Eocambrian (650–570 Myr), dealing with platform clastics and the Ediacara fauna.

There are about 800 references, at least half of which relate to the USSR and China, but most date from the 1960s. A disappointing aspect of the book is the paucity of figures—only 36 with an additional four tables. Two

very useful charts in a back pocket correlate formations in 78 regions across North America and Greenland, and 78 across north-western Europe and the USSR (Britain is missing); and a large table gives a synopsis of all aspects of geological evolution.

Salop is very much better on the younger than the older Precambrian—in fact, his interpretations of some Archaean formations will raise many eyebrows. All gneissic-granulite areas have to be Archaean and their stratigraphy is sedimentary (V. R. McGregor's tectonic intercalations are not considered). Isochrons are said to indicate "rejuvenated" ages dating the period of late recrystallisation. Thus, the Fiskenaesset complex, the Scourian

and the Moldanubian are considered to have "formed" more than 3500 Myr ago, but the Isua supracrustals are included in the Paleoprotozoic. Salop's classification is so rigid that it does not allow greenstone belts to form in one region while high-grade gneisses are forming in another.

The book provides, however, for the first time in English a very valuable correlation of the main formations and rock groups throughout the USSR and China with those "in the west". This is its main contribution.

B. Windley

B. Windley is Reader in Geology at the University of Leicester, UK.

Modern knowledge of cyclic nucleotides

Cyclic Nucleotides in the Nervous System. By John Daly. Pp.401. (Plenum: New York and London, 1977.) \$39.

ONE of the first papers from Earl Sutherland's laboratory about the new nucleotide, cyclic AMP, included observations on the distribution in mammalian tissues of adenylate cyclase, the enzyme responsible for its synthesis. The highest concentration was found in the brain. Thus, it was clear from the start that Sutherland's epoch-making discovery would figure prominently in neurobiology. Development of the significance of this observation was initially due to Sutherland's co-worker, T. W. Rall, who observed that in the nervous system cyclic AMP functions as second messenger not to hormones circulating in the blood stream, but to certain neurotransmitters. Rall's work may be said to have set the stage for the tremendous expansion in the literature on cyclic nucleotides in the nervous system so extensively documented in John Daly's monograph.

Dr Daly's book is entirely orientated to the nervous system; no concessions are made to the general reader unfamiliar with the background to the subject. After a cursory introduction of no more than two pages, he launches into the first of three long chapters, entitled "Enzymatic Formation, Degradation and Action of Cyclic Nucleotides". This deals mainly with the pro-

perties and distribution of adenylate and guanylate cyclases and phosphodiesterases in brain, ganglia and cell cultures, together with a description of enzyme systems concerned in the cyclic AMP-dependent phosphorylation and dephosphorylation of tissue proteins. Next comes an extensive account of the *in vitro* accumulation of cyclic nucleotides in cell-containing preparations of brain, ganglia and other cells of neural or glial origin. The detail here is exemplary, reflecting the author's personal research interests. The final chapter deals with "Functional Roles for Cyclic Nucleotides in the Nervous System". Understandably at this stage of our knowledge it concentrates on actions and effects rather than the physiological functions, of which Dr Daly would be the first to recognise very little is known at present.

The book should prove an excellent text for researchers about to enter or already working in the field. It contains over 1,300 references and is written in a straightforward style that expounds facts and eschews speculation. Such an approach does not always make for easy reading, especially since very little effort is made to summarise or synthesise the mass of information, or indeed critically assess its relative importance. This leads to some repetition and the occasional uncritical citation of dubious work. Dr Daly's book is therefore about the 'trees' rather than the 'wood' but is nevertheless invaluable as an exhaustive source of up-to-date information on modern knowledge of cyclic nucleotides in the nervous system.

R. Rodnight

R. Rodnight is Professor of Neurochemistry at the Institute of Psychiatry, London, UK.

Erratum

● In the review of *Spectrochemical Analysis of Pure Substances* (Nature, 11 August, 268, 572, 1977) the publisher was incorrectly quoted. This should have read: Adam Hilger: Bristol; Crane, Russak: New York.

obituary

Lord Adrian, 1889–1977

LORD ADRIAN disliked his christian names, Edgar Douglas, and was invariably known to his family and friends as Adrian; he will be called Adrian in this article which is concerned mainly with his scientific work, and particularly with the events which led up to the discoveries described in his first two books *The Basis of Sensation* (1928) and *The Mechanism of Nervous Action* (1932).

In order to understand the full extent of Adrian's contribution to science and medicine we must first consider the changes which have come over physiology since he started work with Keith Lucas in the Physiological Laboratory at Cambridge in 1911. It is easy to appreciate the effect of the development of electronic equipment for, as Adrian himself once said, 'The history of electrophysiology has been decided by the history of electric recording instruments'. But there have also been overwhelming changes in ideas and these are harder to take in, for, as historians of science know only too well, it is extraordinarily difficult to put ourselves in the position of our scientific ancestors who did not accept some scientific law or principle of nature that we now regard as self-evident.

One must, for example, remember that although Bowditch established the all-or-nothing law for heart muscle in 1871, in 1911 it was still uncertain whether the same law applied to nerve. The work which Adrian did before 1914 helped to show that in a single nerve fibre the size of the impulse is independent of the strength of the stimulus, provided the latter is large enough to evoke a response; it also removed some of the difficulties which had persuaded scientists as perceptive as Max Cremer or F. Hofmann of the opposite.

Then there was a complete muddle about the contraction of skeletal muscle and it was widely held that the quick and slow movements of voluntary muscle were brought about by different contractile mechanisms activated by two types of nerve fibre, or even by two forms of nerve impulse. This situation was not cleared up until Adrian and Bronk carried out their famous experiments in the late 1920s.

Adrian, who was not at all fussy about laboratory accommodation, has

Douglas Glass

given an entertaining description about life in the old Physiological Laboratory at the time when he started work there. 'In those days the Cambridge School of Physiology was at the height of its fame. It was housed deplorably, judged by modern standards, and run so economically that there was no mechanic and no common stock of tools or apparatus. The research rooms were barely rooms at all. Keith Lucas was lucky to have a small cellar all to himself. It was approached through a larger cellar which housed A. V. Hill and many cages of rats on which Hopkins was carrying out his classical work on the vitamins. A side door led to a dark chamber in which all the frogs were kept and beyond this was the centrifuge driven by a large gas engine of obsolete design which shook the building and added the smell of warm oil and half-burnt gas to that of frog and rat; upstairs worked Barcroft, Mines, [W. B.] Hardy, Anderson, Fletcher, Langley, to name only those who were in permanent occupation, and their accommodation was little better.'

In 1913 Adrian wrote a thesis on *The conduction of the impulse in the nerve fibre* which won him a Fellowship at Trinity College, of which he was later to become Master (1951–1965).

In July 1914 Adrian went to St Bartholomew's Hospital where he qualified in record time, just over a year; he then worked on nerve injuries and shell shock, first at Queen Square and later at the Connaught Military Hospital at Aldershot where he remained to the end of the war in spite of strenuous efforts to get to France.

There are several interesting papers of a clinical nature from this period, but much the most remarkable is one published in 1917 in the *Lancet* with L. R. Yealland on the treatment of some common war neuroses. The paper describes a highly successful method of dealing with hysterical paralysis, which the authors applied with at least 95% success to more than 250 cases, including all the common hysterical disorders such as mutism, deafness, paralysis of limbs and so on. No great originality was claimed for the method which depended on persuasion and suggestion, usually employing electrical stimulation to evoke sensation or movement, but it is evident that the authors applied the method with much ingenuity and understanding of human nature. The article is also remarkable for sympathetic references to psychoanalysis which bear witness to the width of Adrian's interests, as does the manuscript of an unpublished lecture 'Freud without tears' given in 1919.

After the war, Adrian continued for several years with analytical electrophysiology of the type which he had started with Keith Lucas (who was killed in an aeroplane accident in 1916). But about 1925 he began to use valve amplifiers and made what in the jargon of today (which Adrian detested) would be called a break-through.

The transformation is best described in his own words, 'Alexander Forbes had been working with me in Cambridge and I had learned a great deal from him about string galvanometers and about mammalian preparations, but the experiments I had started became more and more unprofitable. You know the sort of thing that happens—they became more and more complicated and the evidence more indirect, and after a time it was quite clear that I was getting nowhere at all.'

Adrian then describes how he had built a 3-stage valve amplifier to the design given him by Gasser and had

connected it up to a capillary-electrometer recording from the sciatic nerve of a nerve-muscle preparation. He was distressed by a rapid electrical oscillation which appeared whenever the muscle was hanging down freely and disappeared when it was supported. Then "The explanation suddenly dawned on me, and that was a time when I was very pleased indeed. A stretched muscle, a muscle hanging under its own weight, ought, if you come to think of it, to be sending sensory impulses up the nerves coming from the muscle spindles, signalling the stretch on the muscle. When you relax the stretched muscle, when you support it, those impulses ought to cease.

"I don't think it took more than an hour or so to show that that was what the little oscillations were. I was able to make photographic records of them, and within about a week I was nearly certain that many of these oscillations were action potentials coming up sensory fibres in the nerve, and what was more, that many of them came from single nerve fibres and that by some extension of the technique it ought to be possible to find out exactly what was happening in single nerve fibres when the sense organs attached to them were stimulated.

"That particular day's work, I think, had all the elements that one could wish for. The new apparatus seemed to be misbehaving very badly indeed, and I suddenly found that it was behaving so well that it was opening up an entire new range of data. I'd been bogged down in a series of very unprofitable experiments and here suddenly was the prospect of getting direct evidence instead of indirect, and direct evidence about all sorts of problems which I had set aside as outside the range of the techniques that one could use. The other point about it was that, as I said, it didn't involve any particular hard work, or any particular intelligence on my part. It was one of those things which sometimes just happens in a laboratory if you stick apparatus together and see what results you get."

The comment that one wants to make about the last sentence is that when most people stick apparatus together and look around they do not make discoveries of the same importance as those of Adrian.

The initial advance made by Adrian was rapidly followed by three important papers with Zotterman which showed beyond doubt that the nerve impulse was invariant, that the intensity of sensation was conveyed by the frequency of nerve impulses and the quality by the type of nerve fibre in action. Another very important point is that adaptation to a steady stimulus takes place peripherally and that some

sense organs, like those concerned with touch, are rapidly adapting, whereas others like muscle spindles are slowly adapting.

These early experiments on sense organs are beautifully described in *The Basis of Sensation* which is written in such simple and elegant language that it is difficult for a student of today to appreciate the novelty and importance of what is being said.

At about this time Adrian's small group was joined by B. H. C. (now Sir Bryan) Matthews who followed up Adrian and Zotterman's work in two classical papers on muscle spindles. Matthews also introduced the oscilloscope which bears his name and which proved extremely suitable for the type of work done by Adrian and his school. Later Adrian and B. H. C. Matthews collaborated in important studies of the Berger rhythm and on the interpretation of potential waves in the cortex; these papers laid the foundation of modern work on electroencephalography in man.

Other famous collaborative papers from the period 1926–1944 were those with Rachel Matthews on the action of light on the eye, with Bronk on the discharge of impulses in motor nerve fibres and with Moruzzi on the motor cortex and pyramidal tract. The paper with Bronk cleared up the long-standing puzzle of the origin of 'tonus' in mammalian skeletal muscle by showing that during weak discharges motoneurons fire at slow rates, ten per second or so, giving an incomplete tetanus in individual motor units but a smooth movement of the whole muscle because the discharges are not synchronised.

In 1937 Adrian who had previously held a Foulerton Research Professorship of the Royal Society, succeeded Sir Joseph Barcroft as Head of the Department of Physiology, a post which required much teaching and administration and which he held until 1951 when he became Master of Trinity.

In addition, Adrian was President of the Royal Society from 1950–1955, of the British Association in 1954 and of the Royal Society of Medicine from 1960–1961, Chancellor of Leicester University from 1957–1971, Vice-Chancellor of Cambridge from 1957–1959 and Chancellor of Cambridge from 1968–1976.

Adrian shared the Nobel Prize with C. S. Sherrington in 1932, was awarded the Order of Merit in 1942 and received a host of other honours which testify to the esteem in which he was held throughout the world; he was made a peer in 1955. He was a superb lecturer and after-dinner speaker and was much in demand in both capacities;

in addition he served on several time-consuming and important committees such as the Medical Research Council, the University Grants Committee and the Chemical Board.

After contemplating the list of positions held by Adrian from 1937 onwards one might be forgiven for thinking that he had little time for research in the Laboratory, or at least that he would be forced to rely mainly on help from colleagues. This was very far from the truth. From 1937 till 1959 Adrian was constantly in the Laboratory and published a number of excellent papers dealing with subjects as diverse as hearing, the sense of smell, vision, the cortex and the thalamus, and using animals as large as a pig or a Shetland pony or as unusual in a physiological laboratory as an alligator or a hedgehog. Much of this work was done alone, Adrian's custom being to dispense with the help of his faithful assistant Hatton as soon as the animal was anaesthetised and a single pair of hands could cope.

Edgar Douglas Adrian was born on 30 November 1889. He read classics at Westminster School and became interested in philosophy, partly at least through his friendship with C. D. Broad. This interest can be seen in all three of his books but most strikingly in *The physical basis of perception* which skates round the problems of mind, brain and consciousness in a most engaging manner. The book also contains a fascinating summary of the experiments which he carried out during the latter part of his scientific life.

In 1923 Adrian married Hester Pinsent who later became famous for her work on mental health; she died in 1967 to the sorrow of a wide circle of friends. Adrian relied greatly on her enterprise and ability and there is no doubt that she made an important if indirect contribution to his scientific achievements. They had three children; Mrs Anne Keynes, Mrs Jennet Campbell and Richard Hume Adrian, FRS who succeeds to his father's title.

After Hester's death, Adrian returned to Trinity, the College which he loved so well, to live in a beautiful set of rooms in the corner of Neville's Court. Until failing health intervened, it was his custom to entertain scholars and many other undergraduates to lunch or dinner about once a week. He remained in Trinity until a few weeks before his death in the Evelyn Nursing Home at the age of 87 on 4 August 1977.

newly on the market

These descriptions are prepared by the staff of *Nature* on the basis of material provided by manufacturers. The Reader Enquiry Card faces the inside front cover.

Peristaltic pumps. ChemLab. Models CPP15SB and CPP30SB for continuous flow analysis incorporate a 'standby' facility which enables the pump to be set to operate for 1 s every 15 s. This gives a minimal flow of liquid to maintain a continuous flow system in readiness for operation but avoids wasting reagents with the pump running at full speed while analyses are not actually being carried out. As soon as samples are ready for processing, the 'normal' button on the pump can be pressed and the peristaltic pump then operates continuously at its standard speed.

Circle No. 42 on Reader Enquiry Card.

Digital thermometer. Markson. A new digital thermometer which combines the convenience of battery operation, portability and laboratory accuracy has a selection of thermistor-type probes which permit a variety of laboratory application such as oesophageal, rectal, skin, and oral temperatures as well as water bath, incubator, cuvette, and air surface determinations. The 3-digit instrument offers a measurement range from -30°C to $+100^{\circ}\text{C}$ in two stages.

Circle No. 43 on Reader Enquiry Card.

Miniature welding torch. British Roto-therm. A precision engineered miniature welding torch. The Little Torch is not much larger than a fountain pen yet has the capabilities of more conventional welding equipment while having a considerably higher degree of accuracy. With tip orifice sizes as small as 0.003 inch, which are jewelled for precise flame control, and the ability to achieve flame temperatures up to $6,300^{\circ}\text{F}$, it is capable of welding the majority of 'weldable' metals and alloys ranging from 0.001 inch wire to 16 gauge sheet. Also, it can be successfully used for welding many other materials including glass and ceramics.

Circle No. 44 on Reader Enquiry Card.

Microbiological Flow Calorimeter. LKB. This instrument provides non-destructive, continuous, direct monitoring of processes in micro-organisms in the conditions found in a culture vessel. Microorganisms are pumped continuously from the culture vessel through the microcalorimeter's flow-through cell. Because of the high sensitivity of the detection method (requires only 10^5 – 10^6 cells per ml), reactions can be assayed directly: only the microorganism and its substrate(s) are required. Microorganisms are unchanged by the assay, and can thus be returned to the culture vessel or used for further assays.

Circle No. 45 on Reader Enquiry Card.

LKB Microbiological Flow Calorimeter

Portable flocculator. Voss. This portable flocculator measures $52\text{ cm} \times 33\text{ cm} \times 18\text{ cm}$, is lightweight and can be carried easily. When the case is opened it acts as a base for the flocculator. It consists of a 4-bank stirring unit with flat propeller blades $60\text{ mm} \times 25\text{ mm}$. The diameter of the stirrer shafts is 6.3 mm and the centre between paddles is 10 cm. When paddles are withdrawn there is a clear height from base to underside of paddle of 15 cm. The stirrers are driven by a geared motor at speeds between 25 and 250 r.p.m. A thyristor control enables fine speed control.

Circle No. 46 on Reader Enquiry Card.

Replica plating set. Embio Equipment.

A labour-saving equipment for the replica plating technique has now been developed which uses glass beads, a picking device, a bead sieve and a new type of replicator. A sterile glass bead is sucked by vacuum on to the tip of the picking device, by covering a hole in the device with a finger. The bead, so held, is dipped into a bacterial colony and immediately transferred to a hole in the sieve, which is in position on a nutrient agar plate. The glass bead is left in the sieve and the procedure is repeated with another glass bead. The bead sieve can accommodate up to 100 beads on a single 9-cm plate. The bacteria-carrying beads are thus inoculating the plate. The beads and the sieve are then easily removed from this plate. Additional replicates of the colonies that appear on this master plate after incubation can be made by using the replicator. Twenty successive replicas are easily obtained.

Circle No. 47 on Reader Enquiry Card.

Digital film thickness monitor. Nanotech. Many vacuum deposition processes require the control and indication of increasing film thickness during the deposition cycle. The model NQC1 is an economical instrument for this purpose. The deposited film thickness is read directly on a 4 digit LED display, a thumbwheel switch allows the density of the material being deposited to be entered to ensure the correct thickness reading using any deposition material. The thickness of the deposited material is measured by the alteration in the resonant frequency of a quartz crystal located close to the material being coated. The maximum thickness that can be measured before replacing the crystal is equivalent to $12\text{ }\mu\text{m}$ of aluminium or proportionately less for more dense materials. Alternative configurations of crystal holder are available to suit different applications. These include water cooled sensors for high temperature ambients, also special filter arrangements to extend the quartz crystal life in high rate deposition processes such as Ion Plating.

Circle No. 48 on Reader Enquiry Card.

Plasma etching unit for electron microscopy. Nanotech. The Plasmaprep 100 includes a Pyrex chamber 150 mm × 100 mm diameter which is externally excited by a variable supply of up to 100 W RF power. Access to the chamber is gained by a vacuum sealed hinged door, the pressure inside the process chamber is controlled by a gas inlet needle valve with associated flow meter. The chamber is evacuated by a rotary vacuum pump to a normal working pressure in the 0.5 to 1.0 torr region. Control of the etching process is simplified as the equipment is semi-automated; when the chamber has been evacuated the RF power can be varied and tuned to match the chamber pressure and loading. The choice of reagent gas dictates the reaction with the specimen; typical gases used are oxygen, hydrogen and fluorinated and chlorinated hydrocarbons. Reaction products are removed in the gas stream.

Circle No. 49 on Reader Enquiry Card.

Nanotech plasma etching unit

Rotating anode X-ray generator. Marconi-Elliott. The new rotating anode X-ray generator operates at currents up to 300 mA at 50 kV on a focus of 0.5 mm. This new high power (15 mA kW) generator greatly extends the field of application and brings the advantage of short counting and exposure times as well as focal spot sizes down to 0.1 mm to all crystallographers in both research and industrial laboratories. It is the first X-ray diffraction equipment to comply in every way with the forthcoming statutory safety regulations under the Health and Safety Act. The GX21 generator has been specially designed to prevent the occurrence of any accidental exposure of personnel to a significant level of dangerous radiation. A transparent radiation shield can be provided to protect the operator from hazards from all diffraction instruments which are not themselves shielded.

Circle No. 50 on Reader Enquiry Card.

Disposable filter units. Variable Volumetrics. Completely disposable miniature liquid and gas filters, Balston Microfibre Disposable Filter Units are

specially packaged for laboratory use in boxes of five filters each and are available in a range of filtration grades which make them suitable for such laboratory functions as filtration of reagents and samples to liquid or gas analysers, filtration of liquids fed to liquid chromatographic columns, filtration of precious metal solutions without danger of leakage, sterilisation of compressed air and other gases, and complete removal of oil, dirt and water from compressed air and other gases. The units are also ideal for use as vent filters on microbiological reactors to prevent loss or escape of microorganisms.

Circle No. 51 on Reader Enquiry Card.

Industrial conductivity transmitter. Philips. The PW 9521, can be used with the Philips PW 9570 flow cell to provide accurate conductivity measurement even when the monitoring electrodes become contaminated. Designed for flow line applications, the PW 9521 automatically compensates for contamination caused by impurities such as oils, fats and emulsions and eliminates polarisation effects, making possible reliable long term measurements with greatly reduced maintenance. When used with a platinum or nickel resistance thermometer, the PW 9521 can be adjusted to provide automatic temperature compensation for a wide variety of solutions with differing temperature characteristics. The PW 9521 can accommodate measurements from 1 ms cm⁻¹ full scale to 1,000 ms cm⁻¹ full scale; the conductivity range being converted to a 0–20 mA or 4–20 mA signal, providing standard inputs to associated monitoring or control systems.

Circle No. 52 on Reader Enquiry Card.

Refrigerated bench top centrifuge. MSE. The Chilspin centrifuge has a refrigeration unit built in and although designed as a bench top model it is easily converted to a floor-standing unit. Chilspin has a maximum speed of 6,100 r.p.m. (6,030g), and four rotors with trunnion carriers and adaptors provide the versatility needed beyond the standard swing-out capacity of 4 × 100 ml, 8 × 50 ml or 16 × 15 ml. Controls include a temperature regulator from +5 to 15 °C, speed indicator, automatic timer and electric brake. Chilspin complies with latest international safety requirements including a positive lid lock, high grade steel guard ring and a hydraulic lid stay.

Circle No. 53 on Reader Enquiry Card.

Column packer. Micromeritics. One of the major recurring costs to the user of liquid chromatographs is column replacement and packing. The Model 705 stirred-slurry column with micro-

particle materials. The pumping unit of any HPLC system can be readily adapted to pressurise the Column Packer which is best used at 6,000 p.s.i. In the 705 the packing material is dispersed in a suitable liquid and then stirred vigorously while being fed into the column. The continuous stirring ensures that a continual homogenous suspension is fed into the column. The technique is simple and fast and it takes about 30 min to pack a 4 mm i.d. × 25 cm column with 10 μm silica gel.

Circle No. 54 on Reader Enquiry Card.

Beckman analyser

Glucose and B.U.N. analysers. Beckman. The Glucose Analyser 2 and BUN Analyser 2 incorporate clinically proven methodologies and advanced circuitry for easier, faster, clinical determination of glucose or blood urea nitrogen. Both instruments are simplified to one-step operation. After calibration the operator injects a 10 μl sample, which automatically initiates analysis. In 15 s the reading in mg dl⁻¹ or mmol l⁻¹ is indicated on the digital display. Three pumps assure fresh reagent in exact measure. A drain pump empties the sample cup, a fill pump refills it with fresh reagent, and a sip pump removes excess fluid until the precise amount remains. Lights on the control panel indicate when to sample and when to read. Instrument chemistries are clinically proven and accepted. The Glucose 2 is based on the oxygen rate method; the BUN 2 uses the conductivity rate method. Both instruments provide answers in 15 s, an advantage in STAT and routine laboratories. Routine output is up to 67 determinations per hour. The 10 μl sample requirement is a further advantage.

Circle No. 55 on Reader Enquiry Card.

Automatic wow and flutter meter. B & K Laboratories Ltd. The 6203 is a small, easy to use but accurate instrument using analogue and digital techniques to measure peak flutter and drift in sound recording and reproduction equipment. It will measure flutter and drift down to 0.001% and 0.01% peak respectively.

Scientists in public

It is traditional for scientists to return to Europe from visits to the United States with their batteries recharged and a whole host of new ideas picked up in haste to be tried out at leisure. And it is equally traditional for those first few days after re-entry to be days of frustration, with limited funds, petty bureaucracy and inferior telephones. Gradually, however, there occurs a readjustment to the Old World and its range of values, almost like a shift of cultural Circadian rhythms. And the British can console themselves with the often-heard assertion that we may not have the greatest industrial vigour in the world, or a very significant growth in Gross National Product, but when it comes to the arts and sciences there are immense riches, and these are continually being fed by bright youngsters who, by some pleasing quirk of genetics or environment, seem to keep on coming in their droves.

Now much of this may well be true, although certainly as far as the sciences are concerned lack of industrial vigour is leading to a lack of new opportunities for young people to use their talents, which in a very short time could lead to young British scientific talent being famed mostly through its widespread presence in the laboratories of other countries. But one area in which the trans-Atlantic traveller certainly ought to notice that the United Kingdom is already painfully lacking in comparison with the United States is in the matter of the scientist and public life. It is not just that science has a more visible rôle to play in the United States, although this is undoubtedly true of a country with a vigorous space programme, a highly technologised military, serious energy problems, a commitment to the latest in telecommunications, micro-processors and so on. This inevitably means a wide, mature exposure for science in the media, with all the concomitant benefits. But it is also that the individual scientist is welcomed much more openly and equally into the discussion of public affairs and is expected not just to make specialist inputs appropriate to his or her discipline, but also to be the broad and balanced person that in Britain the arts graduate is expected to be.

This phenomenon not only occurs through the

existence of the in-and-outer in the higher ranks of public service in Washington—a category, incidentally, which will probably diminish as President Carter's campaign for purity on conflict-of-interest bites more deeply. It is to be seen also in the proliferation of quasi-governmental and private institutions around the nation devoted to public policy, which think it entirely natural to hire—and fire—scientists in numbers. It is certain that amongst them are going to be many who will just conform to the seedy wheeler-dealer image. But the system has thrown up and will continue to throw up many scientists who acquire a grasp of generalities and an overall profundity rarely to be seen in British circles.

Now many scientists on both sides of the Atlantic undeniably want, and should be granted the right to stay perfectly happily out of the public eye, getting on with their research. But as science and society cross each others paths more and more, society ought to be asking a growing number of scientists to abandon their specialisations, even temporarily, and to worry about broader issues.

We have, of course, in Britain an excellent and highly professional civil service, and it performs many functions admirably in the matters of science and public policy. But we pay a price for its very professionalism and that is a resistance to outside pressures. And with negligible movement into or out of the service either by administrators or 'professionals' above the age of about 30 there must be the most serious questions about whether the service doesn't waste genuine human resources. Here is a question which the Commons Select Committee on Science and Technology, if it were to be looking for some new and difficult ground to break, could well investigate. The role of the scientist in British society and the problem of too much compartmentalisation, which discriminates against the free flow of ideas, is a subject of broad interest. The results of an investigation would hardly be spectacular, nor given to immediate and drastic action. But long-term benefits could be substantial if the scientist who so wishes could be encouraged to lead a fuller life and to provide more in the way of public service. □

GDR's state of science

Scientific exchanges with the German Democratic Republic (GDR) are rare, and our knowledge of the state of its science is consequently sparse. A correspondent with some experience of East European countries, who recently completed a trip to several biochemistry and microbiology laboratories in the GDR, returned with these impressions.

THE mood among the scientists with whom I spoke is one of frustration and pessimism. The scientific community is thwarted and repressed by the government, and the situation is, if anything, worsening. I would put it as more critical than, say, in Poland or the Soviet Union. The very possibility of doing research in the GDR was a subject of discussion. The problems are of two sorts, financial and political.

One of my stops was a large city with a prestigious university. The contrast between the newly constructed university skyscraper, to be used primarily for the study of Marxism-Leninism, and the shabby buildings of the science complex made a striking impression. The biochemistry laboratory which I visited was not adequately equipped. The laboratory, with a staff of some 20 researchers, had, for example, no scintillation counter. In addition, some of the equipment which they did possess was of inferior quality. In particular, the ultracentrifuges, of East German manufacture, can be run for only a few hours at a time, or the drive will fail. Aggravating these financial problems is the peculiar bureaucratic regulation that purchases be made only once a year. This both wastes the meagre resources available to the laboratory—chemicals are ordered which are never used—but also leads to spot shortages which may abort an ongoing project.

Hard currency restrictions make subscriptions to Western scientific journals difficult to obtain. The biochemistry group had subscriptions neither to the *Journal of Biological Chemistry* nor to the *Journal of Molecular Biology*. The restrictions also greatly reduce the number of GDR scientists who can attend conferences in the West. At the time of my visit to another laboratory, for example, only one scientist out of some 800 total staff members was in the West. While science was a low priority area, the support of athletics was lavish. The new municipal stadium was monumental. Furthermore, much hard currency goes to support the hordes of javelin throwers, swimmers and runners who are treated to expensive trips to Western Europe and North America.

The political situation complements the economic one. The government plays a very direct role in laboratory affairs. Needless to say, permission is needed to attend a scientific conference outside the GDR, but is also needed, for example, to publish an article in a Western scientific journal. The government can and does direct a laboratory programme; a microbiology laboratory on my itinerary had been ordered to abandon its programme of basic research and to commence work on a project which the administrators felt had industrial applications. Even in basic research, 'plans' are delivered to the researchers detailing experimental 'goals'. With the exception of the Communist Party members of the staff, these 'plans' are largely ignored. Recently, however, it was decided that the laboratories must hire more Party members. For one group, this meant that all future appointments at the level of Laboratory Chief or above would have to be filled by Party men.

The authorities have also found that science administration is a good place to put retired military personnel. In

Camera press

Leipzig, with Karl Marx university in background

some cases these ex-colonels have chosen to classify a laboratory as 'secret', shutting it off from communication with the rest of the scientific community.

Pressure is applied on the scientists to join the Communist Party, but it is my impression that this is far from successful. A valid reason for not joining is the profession of a religious belief, and this excuse is used frequently. Although promotions, trips abroad and other rewards are given preferentially to Party men, these inducements are not sufficient to overcome the moral repugnance which most of my informants felt towards Party membership. Other scientists, less estranged from Communist ideology, spoke of "compromises" that have to be made in order to work effectively.

In spite of these difficulties, science has not been abandoned; research of good quality is still going on. Efforts to keep up with scientific progress are evident. Especially apparent is the enthusiasm with which Western visitors are greeted; the GDR scientists clearly want to establish contacts and exchange ideas with their Western counterparts. If we wish to aid them, we must visit their laboratories and attend meetings in the GDR, since our Eastern colleagues cannot easily leave their country, or initiate contacts with Western scientists. The exchange of scientific information, as well as gifts of subscriptions to journals or of chemicals and laboratory supplies could help science survive. □

IMS at the crossroads

The success of next week's ISEE satellite mission is crucial to the IMS. Judy Redfearn outlines why

PART of the International Sun-Earth Explorer (ISEE), the second major satellite mission in the International Magnetospheric Study (IMS), was due for launch this week aboard one of NASA's Delta launch vehicles. But because of delays to NASA's launch programme caused by the failure last month of the Delta rocket carrying the European Space Agency's (ESA) Orbital Test Satellite (OTS), the ISEE launch has been put back, probably until 19 October. If the launch fails to go ahead then, or at least by the end of the month, it will face a lengthy hold-up because the current period of short daily launch windows will then have passed by; the ISEE mission would have to remain earthbound until next spring.

Magnetospheric scientists will be watching the launch with a degree of apprehension for another reason. Earlier this year, a Delta launcher failed to send Europe's Geos, the first IMS satellite mission, into geostationary orbit. Although the consequences are not as severe as was first thought, the IMS programme has suffered a setback. So the success of ISEE is now more important than ever to the success of the IMS. If all goes well next week, a unique programme will begin to find out the precise mechanisms governing the magnetosphere, the area of the near-earth environment where the solar wind interacts with the earth's magnetic field.

For the first time two satellites, NASA's ISEE A and ESA's ISEE B, are to be launched in tandem aboard a Delta 2914 rocket into the same highly elliptical orbit. ISEE B, the 'daughter', will follow ISEE A, the 'mother', at a distance varying between 100 km and 5,000 km. The satellites will carry carefully matched experiments allowing them both to make comparable measurements of the same phenomena. Because they will be moving at a known speed and distance apart, they will be able to distinguish between transient phenomena and those which are permanent but vary in space. A single satellite suffers from not knowing whether a phenomenon has moved past it or has died out.

Crossing boundaries

Although many phenomena are known to exist in the magnetosphere, they are not well understood because of the problem of distinguishing spatial from

temporal variations. In particular little is known about the processes which occur at the boundary where the solar wind meets the magnetosphere. The highly elliptical orbit of ISEE A and B was designed to maximise the number of crossings of this boundary, or bow-shock, during the satellites' three-year lifetime. The orbit chosen has a 59-hour period with a closest distance from earth of 280 km and a furthest distance of about 140,000 km. It will also carry the satellites through other boundaries, such as the magnetopause, plasmopause and neutral current sheet.

In June next year, ISEE A and B will be joined by the third and final part of the ISEE mission, ISEE C. Unlike A and B, C will be launched into an orbit around the sun at a distance of about 1.6 million km from the earth. For fuel economy, the orbit was chosen to lie on a libration point where the gravitational forces between the sun, earth and moon almost cancel out.

While A and B are measuring processes in the magnetosphere, from its position in deep space C will be monitoring variations in the solar wind and sending information on solar particles back to earth an hour in advance of the particles reaching earth themselves. The data will give a picture of the solar wind which will help in understanding observations made by the A and B satellites.

At the end of the mission, scientists should know a lot more about the solar wind and the processes governing the magnetosphere, which may in turn lead to a better understanding of radio

transmission on earth and some of the mechanisms effecting climate. The magnetosphere, a natural plasma laboratory surrounding the earth, is like the earth's own small universe, the solar wind taking the part of the hot plasma which makes up most of the matter in space and the earth's magnetic field taking the part of the magnetic fields found in space. The study of how ionised particles interact with the earth's magnetic field should yield much about the fundamental processes which govern the behaviour of cosmological objects such as radiogalaxies, pulsars and radio and X-ray stars.

Setting up the IMS

By the late 1960s scientists had a good picture of the magnetosphere, but they knew little of the dynamic processes controlling it. The International Magnetospheric Study was set up as a co-ordinated attack on the remaining problems. To organise the study, the International Council of Scientific Unions (ICSU) Special Committee on Solar-Terrestrial Physics set up an IMS steering committee with representatives from various scientific unions, COSPAR and satellite launching agencies. Thirty-nine countries are now taking part in the IMS, which began in 1976 and is due to run until December 1979.

It is the first international programme of its kind to be based on spacecraft flown by several different agencies. Fourteen spacecraft launched during the IMS period are planned to carry experiments directly relevant to the study and 25 launched before 1976 are expected to add valuable data. But at the centre of the IMS are two spacecraft missions devoted entirely to magnetospheric science—Geos and the ISEE. In addition, Japan is contributing with its magnetospheric satellite, Exos, and Russia with a near-earth satellite.

Cross-section of magnetospheric plasma distribution

The spacecraft programme, however, would be of little value without the numerous ground-based rocket and balloon projects which will continue throughout the IMS period. Earth-based measurements of variations in the magnetic field can be used to monitor magnetic storms and plasma waves and even to predict changes in the magnetosphere. Correlating these measurements with satellite observations should indicate how changes in field strength affect the shape and dynamics of the magnetosphere. Many of the 39 countries which could not afford to be involved in the space programme are contributing to the IMS through a sophisticated world-wide network of ground observatories. Even at the beginning of 1976, more than 1,000 individual research projects were registered on the IMS computerised file.

Many different experimental programmes working towards the same end thus need coordinating. Occasionally, for example, two or more satellites may be in such a configuration that

simultaneous observations would be very valuable. Similarly, satellite observations should sometimes be timed in with ground-based or rocket experiments. To coordinate observations, NASA helped set up an IMS Satellite Situation Centre at the beginning of the study at the World Data Center A for Rockets and Satellites at the Goddard Space Flight Center, Boulder, Colorado. Its function is to report on satellite positions, recommend periods of special interest, compile and up-date information on satellite experiments and answer inquiries on special projects, experiments and the whereabouts of satellites. Every month, the IMS Central Information Exchange Office, also at Boulder, produces an IMS news letter.

Regaining ground

Hopes for regaining the ground lost by the partial failure of Geos hang on the possibility of launching the second Geos satellite into geostationary orbit early next year. The intention had been to place the first Geos in a geo-

stationary orbit 36,000 km above the equator along a field line connecting the north and south auroral zones so that particles on their way to the aurora would pass through it. Ground-based experiments and rocket-borne observations of the aurora could then have been coordinated with experiments on board Geos.

But Geos is not in a geostationary orbit and coordinating observations is very difficult. It would have been impossible had the Geos ground control at Darmstadt not managed to manoeuvre the satellite into a doubly geosynchronous orbit shortly after the unsuccessful launch. Geos now passes through the neighbourhood of the planned geostationary orbit twice a day, meaning that coordinated observations are possible, but only for a very short time. If Geos 2 were launched next year, it could take the place of Geos 1. It would have to be launched on another Delta rocket, however, and ESA might decide to wait until the end of 1979, when it could be launched on Europe's launcher, Ariane. □

WHO's show on the road

Peter Collins describes the gestation of the World Health Organisation's tropical diseases programme

THE temptation to launch global campaigns against specific diseases or conditions of mankind is one the World Health Organisation (WHO) seems unable to resist. The most recent and from all appearances most successful is the smallpox eradication campaign. Pockets of the disease remain, principally in the horn of Africa, but the campaign's objectives are in sight in under ten years. By contrast, in spite of the malaria eradication campaign, which started in 1955, malaria has never been anywhere near eradication in much of Africa south of the Sahara, and is now increasing in other regions and countries where eradication was thought to have been achieved. Now WHO's thinking has turned towards a more broadly-based approach. It is well exemplified by the Special Programme on Research and Training in Tropical Diseases which is tackling six diseases (malaria, schistosomiasis, the filariases, trypanosomiasis, Leishmaniasis and leprosy) that affect some 700 million men, women and children.

Perhaps the greatest single constraint on the development of the tropics lies in the burden of disease borne by their human inhabitants. Probably one in every four people alive

today is at risk from one or more of the six diseases with which the programme is concerned. The position worsens every year as population increases and the world's pharmaceutical industry stands back. No new drug against trypanosomiasis has appeared in the past 20 years; the only drugs available against the filariases have side effects so serious that their use for mass treatment is out of the question; and the drugs used for treating malaria are meeting with more and more resistance on the part of the parasites. Added to this is the increasing resistance of many of the vectors of these diseases to the chemicals used against them, and the many reservations about the use of DDT, still often the most effective weapon for insect vector control.

The sheer lack of scientific knowledge about many of these diseases is also a problem. Not enough is known about the biology of the parasite and the mechanisms by which it eludes the defences of the human host to allow intelligent intervention to be planned. But great advances in such fields as immunology have led to the evolution of a whole armoury of new weapons for the prevention, diagnosis and treatment of disease afflicting richer

WHO anti-malaria emblem

countries, and the question is how these can be made available or adapted to help control the great endemic diseases of the tropical countries

WHO's answer

The present programme is WHO's answer to this question, but it originated within WHO from the conjunction of two quite separate ideas. In 1964 an expert group of immunologists and parasitologists was assembled for the first time in Geneva. Little common ground seemed to exist between these two disciplines thereto: the parasitologists considered that there was little if any immune response to the diseases with which they were concerned, and the immunologists had found ample scope, backed by adequate funds, in fields like cancer research. After this meeting, however, things began to change, and while the immunology of

parasitic diseases was being examined, another initiative was being taken within WHO—the establishment in certain African countries of a network of biomedical research centres, eventually to be staffed and run by local personnel. The feeling was that only research by nationals of the countries concerned could achieve real control of tropical diseases.

It was from a 'meeting of minds' among senior staff involved in these two developments that the present programme evolved. By 1974 their ideas were ready for presentation to the World Health Assembly and subsequent examination by WHO's Advisory Committee on Medical Research (ACMR). The basic plan, further discussed with prospective participants, was developed in time for a major 'housekeeping' meeting in December last year. The pattern is that of a co-operative effort of donor and recipient governments, international agencies and specialised institutions, collaborating with and coordinated by WHO. A major part as co-sponsors will be played by the United Nations Development Programme (UNDP) and (though its precise rôle has yet to be determined) the World Bank. Because the programme involves a number of different WHO departments, a small Tropical Diseases Research Group (TDR) has been set up for overall scientific coordination and management. Progress will be reviewed annually by a Scientific and Technical Advisory Committee composed of scientists, selected on an individual basis, to make the best existing knowledge and experience available to those directing the programme. General oversight will be ensured by a Joint Consultative Board, expected to be convened later this year and designed to represent all the various groups of participants in the programme.

The programme is expected to cost between \$10 and \$20 million a year as presently foreseen. This money will come from governments through their development aid or technical assistance allocations, and from other sources of international funding. It is here that WHO might have anticipated some difficulty, for those concerned with development financing are naturally somewhat cautious when asked to support what is, admittedly, a vast experiment, at a time when funds for development projects are increasingly tight. Several different approaches to this type of financing are already apparent. The Scandinavians prefer to hand over funds directly, often seeming to take little interest in their management, although they may now be looking harder at the results than hitherto. The USA, on the other hand,

appears to favour complete control of the programme funds, preferably by the World Bank. Britain's fairly neutral stand on that point is tempered by an insistence on continuing and critical evaluation of both the selection and progress of individual projects. Even at this early stage, several governments, Britain's included, have been highly critical of the potential of certain projects to which programme funds have been allocated by WHO. Intriguingly, it does seem that one problem is to find sufficient projects to absorb the funds already available, a situation that should reassure those who fear that the programme will prove to be yet another drain down which development funds are being uselessly poured.

Two lines

The two main lines of action that make up the agreed programme reflect its dual origin within WHO. The first is a vastly increased research effort directed at some of the main problems of the six selected diseases, and involving many of the ideas and techniques developed by biomedical research into the diseases of the industrialised, affluent world. Where possible, this research should be done where the diseases occur, and eventually (though this is not yet feasible) by nationals of the countries concerned. The second recognises that research, however successful, is of little use unless it can be properly exploited. This means training nationals of the tropical countries in the design, administration and application down to village level of whatever control system is finally evolved.

The underlying approach is not without precedent as far as WHO is concerned. Its programme for research into human reproduction was set up on much the same lines: a group of scientists was assembled, presented with certain ideas, asked if they thought a programme based on these ideas could be made to work, and urged to indicate the steps to be taken. This in itself was something rather new; biologists are not usually asked to do research with a definite end in view, and the human reproduction programme is one of WHO's current successes. That the system can work is also shown by the Scientific Working Group on the immunology of leprosy, which was set up in the same way and is already yielding results.

The parasitic diseases programme is of a different order of magnitude, though. Each of the scientific working groups is in itself an experiment directed to separate objectives. Apart from those dealing with leprosy, groups on filariasis, schistosomiasis and the immunology of malaria have been set up; others will be concerned with

such broad fields as vector biology and the tissue culture of parasites. Each group examines its particular disease under headings like immunology, chemotherapy, epidemiology and training, and identifies desirable research projects and the institutes and individuals to tackle them. WHO envisages a network with a coordinating group at headquarters. On the one side are the 'collaborating institutes', the established centres of biomedical research, mostly located in the industrialised countries. Their collaboration will be sought for the more sophisticated research especially where new and special equipment and facilities are needed, and for training at the higher levels. On the other side are 'collaborating centres', at various levels from large university departments to small laboratories employing only a handful of qualified staff, and located mostly where the diseases are prevalent. It is in this group that the 'institution strengthening and training activities' of the programme will have first priority.

No cutting

As WHO sees it, there is no need for the programme to cut across the activities of the established institutions in the industrialised countries. But with too many people doing research into tropical diseases who have had little or no contact with those suffering from them, a properly coordinated operation of such a network should help progress. WHO would make a further point, that the programme offers opportunities that are, scientifically speaking, exciting, with the use of the new tools and high technology of modern biological science. The different approach to publicising the programme reflects this. In the past, publicity has been given to global programmes of public concern, with the aim of telling people about something being done for their welfare—the conquest or alleviation of rheumatism, for example (1977 is World Rheumatism Year). For the tropical diseases programme, WHO's aim is rather to interest the scientific community.

With the gradual run-down of the great colonial medical services, tropical disease research has been increasingly less popular. But now, the more people who know of this vast new programme and of its funding, the greater likelihood there is of interesting young research workers in the opportunities it has to offer. And at some \$20 million a year for, say, 20 years, it is not that expensive. A major pharmaceutical company can spend five times that annual sum in a single year, and some countries spend as much on cancer research as the total budget for this research on tropical diseases. □

BRITAIN

Blunt then blunted

The UK Medical Research Council (MRC) published its latest annual report earlier this week. Chris Sherwell reports

APART from being mere snapshots of the period they describe, annual reports suffer by emerging halfway through the following year. Introducing the first report since he became MRC Secretary, James Gowans quickly addressed one problem by communicating a vivid impression of the dynamic quality that informs current medical research. But the need to bring everyone up to date blunted the impact of the report's potent, if measured, criticisms of the way some of that research is now run.

The report, which is for the twelve months to March, describes the impact of a £1 million (10%) cut in commissioned research from the Department of Health and Social Security (DHSS). It says the Council was "deeply concerned" at the size and suddenness of the reduction, which "disrupts financial planning and frustrates initiatives" and affects both commissioned and other research. But the outlook was now less bleak, Gowans told his audience. The DHSS would be giving back £700,000 next year, and the MRC "firmly expected" a 1.6% real increase in its share of the Science Budget in the coming year.

Gowans was apparently concerned also to moderate the tone of the report's criticisms of the operation of the customer-contractor principle, under which the DHSS acquired control of one-fifth of the MRC's funds. A series of rhetorical questions in the report suggests that responsibility for any lack of orientation of research work to social objectives cannot be laid at the MRC's door. The report also describes at length how administrative work and accountability requirements have imposed heavy burdens and taken experts away from research—"a high price to pay" for arrangements which could be achieved "with less

formality and administrative expense"

Gowans amplified the first of these points and dwelt not at all on the second. He described specific cases—the latest being the Blood Group Reference Lab—of the MRC deciding to start something new and then handing it on to an enthusiastic government; the MRC, he said, was anticipating national needs long before the customer-contractor principle came along. The ease with which the MRC programme merged with DHSS requirements, he added, also vindicated the MRC's judgment; the DHSS wanted the MRC to do what it was doing anyway. But the conclusion he drew was that DHSS-MRC relations were very close. The "one proviso" was a complaint about bureaucracy.

If these pulled punches reflect the happy amelioration of financial problems, other thrusts in the report indicate that additional anxieties remain. The organisation of clinical research is "becoming increasingly difficult" as the incentives for young doctors to do research have diminished, and there is an "apparent tendency to lose sight of research as a proper component of clinical training". An appropriate pattern of support for university research when universities are not expanding has also yet to emerge, and is "of crucial importance" if the flow of able young scientists into research is to continue; holding research teams of high quality together will be "increasingly difficult" unless the problem of low numbers being absorbed into permanent university appointments is solved.

In the stringent economic circumstances the Council describes its first priority as reducing long-term commitments in order to free money for new work. Competition for long-term support will thus be fierce, it says, but short-term awards will now increase, and it urges the scientific community to continue to apply for these.

On the subject of recombinant DNA experiments, the MRC says it is looking forward to receiving proposals (four

large project grants have already been made to universities); "high priority" should be given to the provision of centralised facilities for category III and IV experiments. The MRC in fact has no plans to build a category IV facility. The future of the only one in the country, the Microbiological Research Establishment at Porton, is now under consideration by the government. An MRC committee set up to examine the possibilities it offers is due to report soon □

Research report

THE massive UK Department of the Environment (DOE) last week released a slim fourth annual report on research and development—covering a period that ended a full 18 months ago. A press release accompanying the report, which deals with the last full year before the department was divided into the Departments of Environment and Transport and before Martin Holdgate succeeded Dennis Lyons as Director General of Research, does not explain the delay. But it does advise, without amplification, that recent organisational changes under Holdgate will be described in the 1976-77 report. Holdgate is also expected to outline them to the press next week.

In the meantime, some of the details are available in the September issue of *Environment and Transport World*, the newspaper of the two departments. They are not exactly minor but, unsurprisingly perhaps, a couple are apparently mere name changes; thus, the Directorate of Research Requirements has become the Directorate of Research Policy, and the Research Secretariat has become the Research Administration Division. The Systems Analysis Research Unit (SARU), on the other hand, which has been looking at global problems (see page 356), has not changed its name but is, according to the paper, "increasingly turning its attention to problems on the domestic front".

Perhaps the most important change is the reduction from fifteen to six in the number of internal Research Requirements Committees. These will consist of what Holdgate calls "triads", three-man teams with a representative from the policy side who want particular work done ('customers'), from department research establishments or other research centres ('contractors'), and from the central research policy division. The six committees embrace areas controlled by senior civil servants like planning, countryside and resources, transport, construction and environmental protection.

As for last week's report, it says expenditure on research (at a peak of some £45 million for 1976-77, of which about a quarter went on environmental pollution and resources) is expected to decline sharply to a level in 1978-79 close to that five years ago. This, it says, is a result of constraints on public expenditure and reductions in civil service manpower.

Chris Sherwell

Five-year pattern of MRC expenditure

	Total Expenditure (£million) ¹	Change % ²	Real change % ³
1972-73	28.510 (1.737)	+14.3	+4.1
1973-74	30.330 (5.765)	+ 6.4	+2.5
1974-75	36.293 (8.745)	+19.7	-1.3
1975-76	47.140 (13.148)	+29.9	-0.9
1976-77	52.166 (13.315)	+10.7	+0.9

¹ Figures in brackets are income within the total from sources other than the MRC's allocation from the Science Budget (eg. government departments, health authorities)

² Change in total expenditure over previous year (undeflated)

³ Change, in real terms, of MRC allocation from the Science Budget, over previous year

USSR

Exchange agreement

In spite of new agreements, there is scope for more scientific visits between the UK and USSR. Vera Rich reports

A NEW agreement on the exchange of scientific visits was signed in Moscow last month by Lord Todd on behalf of the Royal Society and Academician Anatolii A. Aleksandrov for the Soviet Academy of Sciences. Although the negotiations took place in what Aleksandrov described as a "friendly and constructive" atmosphere, and although Lord Todd told *Nature* that he felt that "good progress had been made", the details of the latest agreements reveal just how much progress in scientific exchange still remains to be made.

The new agreement provides for a two-way traffic of seven senior and four junior visits per year. Senior scientists will visit the host country for 3–6 weeks and junior scientists for 8–10 months at a time, the total yearly

quota being 40 man-months. This seems negligible compared with the 50–100 short-term visits per year between the UK and the major EEC countries or with UK–Poland exchanges, where there is an annual flow of some 80 visits to Britain and 40 visits to Poland. Leaving aside the special case of the English-speaking countries, one would expect the flow of exchange visits to be roughly proportional to the size and scientific importance of the country concerned. The anomalous position of Soviet–UK exchanges is apparently recognised by both parties; according to Lord Todd, both sides agreed that in so far as finances permit, they would like to see the number of exchanges increased, especially among junior scientists.

There is no great enthusiasm in the UK, however, to take up even the number of exchange places available. One reason is obviously language; most Soviet scientists have at least a reading knowledge of English, but the need for a reciprocal knowledge of Russian has

largely been obviated in recent years by the expansion of cover-to-cover journal translation programmes. It is also extremely difficult for young British scientists to discover how they would benefit from an exchange visit.

The Royal Society delegation pressed for more explicit information on the work being done at the various Soviet Institutes. They were assured that intending visitors could find all they needed to know from journals such as *Priroda* (Nature) and *Nauka i Zhizn* (Science and Life). These semi-popular journals are, in fact, designed to give a general idea of current progress rather than to specify the work of individual scientists or institutes; moreover, they are in Russian (the translation programmes deal with specialist journals only), as is the more informative *Vestnik* (Bulletin) of the Academy of Sciences.

The new agreement does, however, include one rather promising provision—the extension of joint research projects. Working visits between the teams involved would not necessarily come out of the 40 man-months of the basic programme. □

USA

Rock energy

David Davies reports from Washington on the US programme to exploit geothermal energy

WITH the United States importing nearly half of its petroleum now, it is no wonder that even modest contributions to the nation's energy budget assume a growing importance. The geothermal energy programme in the US Department of Energy (DOE) could only displace a few per cent. of the nation's fossil fuel requirements by the year 2000 but is authorised this financial year to spend \$116 million, double last year's authorisation and nearly five times the figure of four years ago.

Resources are divided into three categories of increasing magnitude but also of increasing difficulty of exploitation. Convective hydrothermal resources comprise both dry-steam systems, of which the Geysers field in California (extracting 500 MWe at present but eventually 2,000 MWe) is probably the only US example, and liquid-dominated reservoirs, of which there are many at temperatures upward of 90° C. Geopressured resources consist of methane dissolved in water at

moderate temperatures. The water is in isolated reservoirs at the pressure of the overlying rock, much greater than the hydrothermal pressure, and heat, methane and hydraulic power can all be extracted. The resource is concentrated around the Gulf states. Finally there are 'hot dry rocks', rocks at relatively high temperatures near the surface into which water must be introduced to extract the heat.

Dry steam already provides 5% of California's electrical needs at a very attractive price and has needed little government support. Liquid-dominated reservoirs, on the other hand, have needed a stimulus; DOE has just issued a request for bids to build a 50 MWe demonstration plant in the western United States that will be economic and socially and environmentally acceptable. The department hopes to sign a contract for this in mid-1978. But the real and growing optimism, according to Dr James Bresee, director of the programme, is in the potential of the hydrothermal resource for direct-heat applications.

Geopressured resources have a much larger question mark against them. There are major unanswered issues of reservoir producibility and longevity, and so far there has been little com-

mercial interest. Nevertheless, DOE plans to go ahead this year with well-tests in Texas and Louisiana, and has proposed pilot plants for energy recovery.

The hot-dry-rock experiment at Los Alamos, although it has attracted the widest attention, must at present be regarded as the most speculative of all. A fractured zone has been created at a depth of 3 km in granite, and water is run down one pipe, through the granite, and up through a second. The rising hot water flashes to steam. Less than 10% of the water is lost underground. So far the heat extracted (about 3 MWt) is less than had been expected, so the next few months will be a crucial time for this programme.

Not all the obstacles to geothermal energy are technical. DOE employs about six professionals simply to look at the so-called institutional barriers—tax laws, environmental regulations and so on. At last count at least six governmental departments and over ten major agencies are involved in some way or another. Further, although the federal government has established loan guaranties for up to 75% of any loans to the geothermal industry, the widely-expected flood of applicants has not materialised; so far only two guaranties have been made, apparently because large companies would rather act as their own guarantor. □

CANADA

Add minister

The Canadian cabinet has a new science minister. David Spurgeon reports from Ottawa

CANADIAN scientists are once again feeling hard done by as a result of a federal government cabinet shuffle. Hugh Faulkner, Minister of State for Science and Technology since 1976, has been shifted to the portfolio for Indian and Northern Affairs, and a new science minister, J. Judd Buchanan, appointed in his place. He is the fifth minister to have been appointed since the ministry was established about six years ago.

Grumbling was also heard when Faulkner was appointed just two years ago. But in his short time at the post he earned the respect of many in the scientific community by his obviously sincere concern, his interest in the field and his desire to learn. He did not come to the ministry with what many scientists felt was the ideal background. He nevertheless took time to listen, and many scientists feel they have now lost an ally if not a friend. All Faulkner's homework will now go for naught, and Buchanan will have to start over again.

The shift is still more galling for the scientists inasmuch as it indicates once again that the federal government does not take science seriously. For apart from Buchanan's own lack of familiarity with the field, the task becomes once more a part-time concern of its minister. When C. M. Drury held the portfolio, he also held that of Public Works.

Buchanan will now revert to that arrangement, but he'll have even less time than Drury to think about science because his job has been as a sort of 'lieutenant' for the Liberal party in Ontario. Buchanan went from the ministry of Indian and Northern Affairs to the less onerous Public Works portfolio before coming to Science and Technology in order to have time for these political duties. Now some are wondering how he is going to deal effectively with all three areas.

Some very senior scientists, indeed, are beginning to question the usefulness of a system that depends on firm and effective communications lines being established between a minister and the scientific community, and then breaks these lines with impunity just when they have become established. Perhaps the new minister will be able to prove they are wrong, and that such a system can work well after all. It is a heavy responsibility. □

WEST GERMANY

Solar sell

Werner Gries reports from Bonn on state support for energy research

WEST GERMANY'S support for energy research developed a stage further last month with the announcement from the federal Minister of Research and Technology, Hans Matthöffer, of a large programme of support in the field of solar energy. The federal government has supported research into direct and indirect utilisation of solar energy since 1974, and the new programme, *Technologies for the Utilisation of Solar Energy*, makes available a total of DM166 million over the four years 1977-80 to supplement expenditure by private industry.

Some 76% of the country's total energy requirement goes on heating, and 24% for lighting and power. Space heating alone absorbs 40%, mainly through burning mineral oil. Solar energy is therefore important because it can be used for such low-temperature purposes as hot water supply and heating in residential buildings; but its low intensity and its variability mean an efficient technology is needed. Solar radiation per square metre in Germany is only half that in the USA.

The government's measures to promote solar energy hitherto have extended to 50 projects, requiring a total contribution of DM50 million of government money. Chief of these have been the development and long-term testing of novel types of solar collectors. At the same time mass production processes for solar collectors are being developed and a few demonstration plants both in public installations as well as in the private sector have been built with government funds.

Results so far show that it is technically possible even in West Germany to satisfy fully the heating requirements of a well insulated single-family house with solar energy. The necessary systems and appliances are already being offered on the market but the financial outlay is so high that it does not pay to put them in at present. Therefore, in addition to their R&D measures, the government introduced at the beginning of September a programme to encourage energy-saving investments. This grants allowances of 20% of installation costs for insulation, heat pumps and solar appliances.

The conversion of solar energy for purposes other than low-temperature heating has lower priority, but the federal government is promoting R&D in electricity generation to open up new export prospects for German in-

dustry in countries which have plenty of sun. Solar collectors for hot water supply will receive support in the future. Private investment will be rewarded by allowances, model public building measures will explain the new techniques, and standardisation of the most favourable appliances will have an important place in government promotion measures. But the extension of solar installations for space heating depends on the development of energy storage systems, and R&D in this area is being intensified. Solar engineering systems for heat production up to 200 °C are another important focus of research, and the government is making funds available for demonstration plants to show their practical application.

In another trench on the energy front, meanwhile, discussion of the advantages and disadvantages of breeder reactors and the risks attached to them is becoming more heated, notwithstanding the recent unexpectedly quiescent demonstration at Kalkar, the site for a 300 MW prototype breeder. A recent court judgment called into question the construction of the reactor when the judges requested the Federal Constitutional Court to inquire into whether the building of breeder reactors is consistent with the law as it stands at present.

Arguments have persisted in parliament. The Minister of Research and Technology is responsible for financing the development of breeder reactors, and he has given the Bundestag a detailed account in support of breeder development. A total of DM3,000 million has been distributed by the state for research work in this field, annual expenditure is running at DM470 million, and 8,000 people are employed in research, development and construction. Development is marked out up to 1982 with the prototype at Kalkar and the Franco-German *Superphénix* in France.

Though the idea is being aired of severely reducing breeder reactor development to no more than a minimum, the minister has come to the conclusion that cutting the building work on the prototype would cost just as much as terminating it. Many contracts have still to be fulfilled and high social costs would accrue in paying off workers and paying the stipulated penalties for the co-partners in Belgium and the Netherlands. The government maintains that plutonium presents no unjustified risks, contending that the technology can be mastered and that the potential danger is no greater than with a lot of other materials. □

IN BRIEF

USSR space set-back

The cancellation this week of the *Soyuz 25/Salyut 6* link-up is a serious set-back to the Soviet space-programme and a blow to its prestige, especially as some major exploit to mark the 60th anniversary of the October Revolution was widely expected. It also stresses, once again, the great reliance placed by Soviet planners on automatic control even of manned spacecraft. According to the Tass announcement, the two craft were automatically brought close together, and then a docking operation was carried out from 20 metres. "Deviations from the planned docking regime" led to the decision to abort the mission.

Antarctic meeting

The main achievement of the Antarctic Treaty meeting, which ended in London last weekend, was to agree on interim arrangements for conserving marine living resources. Details were not immediately available but the drift of the discussions has been clear.

First the agreement is voluntary. Second it looks at this stage as if it will be confined to restraints on catch quotas of krill and the exchange of statistics. The agreement can only be temporary because West Germany, which has been active in the field, is not a signatory of the Treaty.

The Treaty powers have also agreed to extend their voluntary moratorium on minerals exploration and exploita-

tion. Experts attending the meeting think that it will be at least five years before enough scientific data has been accumulated to assess the likely environmental effects of any exploration and exploitation.

Telescope agreements

ESA is to contribute a faint-object camera and a solar array to NASA's Space Telescope programme under an agreement signed last weekend. The telescope is due for launch in 1983.

Progress has also been made in the Dutch-American Infra-red Astronomical Satellite (IRAS) project with the award last week of a contract for construction of the satellite by the NIVR in Holland.

EVEN the sophisticated generally believe what they hear on the radio, or see on television. A few days ago these media prominently featured a report by the UK Department of the Environment which apparently dealt with the world's future. Listeners or viewers (I was both) received the impression that a group of economists and scientists had engaged in a complicated and detailed exercise, using sophisticated mathematical models and advanced computers, and after years of hard grind had come up with the conclusion that if the world's population continued to grow exponentially at something approaching 3%, in fifty or more years the forebodings of Malthus, first put forward nearly two hundred years ago, would be realised, and mass starvation would overtake mankind. Other shortages, including that of energy, would be less serious.

My reaction was that here was yet another expensive and pointless exercise, over-supported by government funds, discovering something which was obvious to anyone with a little knowledge of these problems. We have seen many such useless exercises in the past, the most notorious being a Cabinet Office report on Energy; this was obviously just another example of governmental irresponsibility wasting the taxpayers' money.

Before expressing this view, however, I waited until the next day, expecting to find a fuller summary in the serious daily press. I found no mention in the *London Times*, the *Financial Times*, the *Guardian* or the *Daily Telegraph*. I did not consult the tabloids. Now I've received the volume which stimulated the radio and television but did not interest the newspapers. It is Research Report 19 from the Systems Analysis Research Unit

(SARU) of the UK Departments of the Environment and Transport, and is called "Sarum 76: Global Modelling Project". It extends to some 230

Model report

KENNETH MELLANBY

pages, and as it costs no less than £15, is not expected to have a mass circulation.

My reactions to the document are quite different to those stimulated by the radio. It is no facile statement of the obvious. I assume that it did not interest the newspapers because it draws no conclusions, contains no pithy summary forecasting doom, but is a serious and careful study, adding another useful volume to the series of reports from these two government departments.

The writers of Sarum 76 (anonymously, only the Director's name appears) have got together an immense amount of information about

world incomes, populations and their changes, energy, renewable and non-renewable resources and agricultural productivity. The figures and tables alone make the volume worth its inflated price. The team has produced a sophisticated mathematical model which, if you think modelling is worthwhile, is itself a model (in another meaning of this over-used word) for this type of study, and it will clearly be useful for others with similar interests.

The report shows that Sarum 76 can be used to test many reasonable assumptions for the effects of any number of permutations and combinations of the changes in population, productivity, climatic conditions and all the other known factors which may affect our future. It makes no claims to foretell the future, and admits that this is not the ultimate, perfect model for this purpose. There is indeed a figure, reminiscent of some in *Limits to Growth*, which shows that if the world population grows at 2.27% a year, food supplies per head could increase for fifty years and then fall rapidly, but this should be seen in the context of many other possible forecasts.

We are now wedded to acronyms, but where those have existing meanings they should be used with care. ASH is undoubtedly suitable for Action on Smoking and Health, but in England Sarum is the old name for the city of Salisbury, and our Established Church adopted the Sarum Liturgy in 1542. Its use brought back to my mind a limerick—in England, incidentally, Hampshire is commonly abbreviated to Hants:

There was a young curate of Salisbury
Who used to be most harum-scalisbury
He went through Hampshire
Without any pampshire
'till his bishop said he must walisbury

correspondence

Research 'ridiculous'

SIR,—Regarding your editorial of 8 September, it seems to me that the Psychological Association and Dr Shockley and Dr Huxley have all missed the point. The proposed research may be desirable or deplorable, but above all it is ridiculous.

Dr Shockley proposes the existence of close linkage between the (unknown) polygenes for skin colour and the (unknown) genes that determine (unmeasurable) absolute intelligence. Even the existence of "absolute intelligence" is unproven and debatable.

For present day genetics and psychology to tackle this problem is like Antonie von Leeuwenhoek studying the structure of the ribosome. Maybe it will be possible some day, in the far future, by which time, hopefully, we will be getting excited about something other than race.

Using hyphens

SIR,—I heartily endorse J. Faber's plea (19 May, page 202) that semantically essential hyphens be reinstated in compound adjectival phrases. The current practice of abandoning this punctuation nearly always generates serious ambiguity, or even utter gibberish. Thus, a printed label on a recent pharmaceutical product advises me: "Do not take with milk or calcium containing antacids." (In this instance one must presume the reference is to *low* calcium, since a recent report in a reputable journal refers to "high calcium containing phospholipids".)

Faber rather charitably attributes this widespread offence to "sheer sloppiness", but my experience has been that the problem stems largely from a deliberate editorial conspiracy. Critical hyphenation is commonly deleted between manuscript and galley, and frequently the deletion is enforced over the authors' protests concerning the resultant semantic atrocities. If one encounters the phrase "men chasing women" in print, the prevailing editorial policy makes it impossible to conclude which group of participants is pretending to be in flight.

Solar nuclear waste disposal

SIR,—It has been recognised for some years that nuclear (fission) reactors are power sources for which there is an increasing need in view of growing world demands for power and depleted fossil fuel supplies. Such power reactors provide a reliable bridge to new power technologies, such as fusion and solar energy collection, which are under long term development.

However, serious questions are rightly asked about the real and imagined safety aspects of the increased proliferation and use of fission reactors of various types. One principal area of concern is the need to find acceptable and safe long term methods for disposal of spent nuclear fuel. Many have yet to be convinced of the conventional wisdom of burial of such wastes in deep ocean trenches or in deep stable rock formations.

In the light of our undoubted need for increasing access to nuclear power, coupled with parallel needs for safe disposal of nuclear wastes, I suggest that serious consideration be given to the application of existing space technology to transport such wastes to the sun.

Reliable space transport systems have been developed in a number of countries during the past two decades. They culminate in the Space Shuttle System. Within the next few years the Shuttle will be making regular, and almost routine, manned journeys between the earth and earth orbits to perform a wide variety of tasks. These include transport and operation of Spacelab, launch of satellites, recovery and manipulation of payloads in space using the Remote Manipulator Facility, deployment of Space Telescope and so on.

It is thus suggested that serious thought should be given, at an international level, to the possibility of using Shuttle or Shuttle technology to carry, on a regular basis, safely encapsulated containers of nuclear waste into temporary parking orbits above the earth from which they can be assembled into payloads for vehicles (also carried into orbit by Shuttle) to carry them on to the sun. The development of such a 'sun-bus' system including its propulsion and guidance components is well within the capability of contemporary space technology.

The writer does not overlook the

many economic and safety aspects of this proposal which will have to be considered in the development of this application of space technology to the service of all mankind. It would appear to be as attractive, if not more attractive, from many points of view, as the current terrestrial nuclear waste disposal methods which are used or which have been proposed. It has the strong advantage of not imposing a social burden lasting for many centuries for the monitoring and safeguarding of our legacy of nuclear waste.

Space Science, Ontario

Farm energy

SIR,—In his recent contribution Kenneth Mellanby seems determined to show us that everything is for the best in the best (ours) of all possible worlds. When it comes to energy use in farming he should be more careful: one man's objective view is another's blind prejudice.

Although our use of energy in farming looks modest by comparison with our profligacy in other directions, it is monstrous by world standards. If all those bushmen, whose energy economy he derides, were to adopt our farming methods they would use all their countries' usual energy supply in the process. If they were foolish enough to adopt our food processing habits as well 40% of the global energy supply would be required.

Although it is possible for several people to be fed from 1 ha, farmed by modern methods, that is not what happens; something like 0.7 ha and half a tonne of oil a year are needed to feed each and every Briton. Of course we have got used to all this, and it would be politically awkward to change, but that is not to say we have a God-given right to carry on. As Gerald Leach says in his book *Energy and Food Production*, "this is quite clearly not a viable system for all time".

Finally, I cannot share Mellanby's optimism that we are responding adequately to the problem he seems so intent to minimise. The main driving force of technical change in food production is towards economy of labour use. I see no sign of significant reductions in energy requirements.

New look at the aminergic nervous system

from Key Dismukes

THE aminergic neurotransmitters—noradrenaline, dopamine, and 5-hydroxytryptamine—have been studied with an intensity far disproportionate to the tiny fraction of brain cells which contain them. This attention has been drawn by the realisation that many clinically important psychoactive drugs apparently operate by altering availability of one or more of these transmitters. New histochemical techniques for mapping aminergic projections are revealing striking anatomical features and hint at mechanisms by which these neuronal systems may shape emotion, vigilance, and learning processes. For instance, almost all of the brain's noradrenaline is contained in a few thousand neurones originating in tiny nuclei in the brain stem. These few cells, however, innervate the entire cerebral cortex and much of the underlying diencephalon, as well as the cerebellum. To accomplish this diffuse innervation, the axons from each noradrenergic neurone must branch perhaps a hundred thousand times.

Several laboratories have reported a startling feature of these ascending aminergic projections. Only about 5% of the axonal varicosities from which neurotransmitter would appear to be released are associated with postsynaptic neurones. The remainder lack the close cellular apposition, subsynaptic web and postsynaptic membrane thickening which characterise classical synapses in electron micrographs. The implication is that the majority of amine-containing varicosities release neurotransmitter which must diffuse to remote receptors, a mode of operation intermediate between the private addressing of classical synaptic messengers and the broadcasting of neuroendocrine secretion.

The technique used in these studies was adopted by the Descarries group at the Université de Montréal from a

procedure developed by Aghajanian at Yale University. Radiolabelled noradrenaline or 5-HT is topically applied (*in vivo*) to a region of the brain for just long enough to be preferentially accumulated by noradrenergic or serotonergic neurones. The tissue is then prepared for autoradiography and examined by electron microscopy. Specificity of labelling was verified by demonstrating that neuronal accumulation of label was blocked by inhibitors of specific uptake or by lesions which selectively destroy one class of neurones.

³H-noradrenaline applied to rat cerebral cortex was found to be taken up and distributed in noradrenergic neurones in a pattern closely similar to that of endogenous noradrenaline (Descarries *et al.* *Brain Res.* **133**, 197; 1977). The radioactive label dispersed along tiny diffusely projecting unmyelinated axons, which have small enlargements spaced at frequent intervals (1–3 μ m). Label was highly concentrated in these axonal varicosities, and was mainly associated with numerous small agranular synaptic vesicles. Although these varicosities have the appearance and inner structure typical of classical synaptic boutons, less than 5% showed signs of being connected to postsynaptic membranes (as opposed to 50% of unlabelled boutons in the surrounding neuropil). Labelled boutons making synaptic contact could not be distinguished morphologically from those without synaptic junctions.

Such non-synaptic boutons may turn out to be a common characteristic of brain aminergic systems. The axonal projections of cerebral serotonergic neurones closely resemble those of noradrenergic systems, with only about 5% of boutons marked by ³H-5-HT evincing synaptic contact (Descarries *et al.* *Brain Res.* **100**, 563; 1975). Chan-Palay has shown that the extensive plexuses of serotonergic axons lying on both sides of the ependymal walls of the ventricles, in the arachnoid sheath around cerebral blood vessels,

and in the pia over the spinal cord have numerous axonal boutons but lack post-synaptic structure (*Brain Res.* **102**, 103; 1976). Earlier approaches to tagging aminergic projections suggested the existence of non-synaptic varicosities in (presumably) dopaminergic endings in the striatum and in catecholamine and indolamine terminals of the median eminence (see references in Chan-Palay *op cit.*).

It is important to note that in none of these systems have the axonal varicosities yet been shown to release their sequestered amines. However, indirect evidence suggests that release does occur. The non-synaptic boutons have all the components normally associated with neurotransmitter secretion. Furthermore, it seems unlikely that the large fraction of aminergic neurotransmitter content which can be released by depolarisation *in vitro* or stimulation *in vivo* could be accounted for by the small fraction of boutons with synaptic contact. Release from non-synaptic boutons is known to occur in sympathetic neuromuscular junctions, such as in the vas deferens.

What is the functional significance of these non-synaptic axonal boutons? The lack of close apposition to postsynaptic membranes implies that receptors for released amines must be distributed farther afield than in classical junctions. 5-Hydroxytryptamine released into the cerebrospinal fluid of the ventricles could be carried to wide areas of the brain. Similarly, the diffuseness of ascending noradrenergic and serotonergic projections would allow distribution of aminergic neurotransmitters throughout the forebrain. Descarries and coworkers estimate that the cortex contains some 330,000 noradrenaline varicosities per mm³, with remarkably uniform distribution. Thus, every cell in the cerebral cortex may lie within less than 30 μ m of a non-synaptic noradrenergic bouton. This arrangement suggests that release of noradrenaline would alter the activity

of large populations of cells, rather than controlling individual targets on a one-to-one basis. Both Chan-Palay (*Cerebellar Dentate Nucleus* Springer-Verlag, 1977) and Descarries *et al.* (*op. cit.*) speculate that these aminergic systems may be used as neuromodulators, biasing the responses of target cells to classical neurotransmitters and shaping the activities of large neuronal regions.

Regardless of whether non-synaptic boutons turn out to release neurotransmitter, a neuromodulatory role for these diffuse aminergic projections is suggested, both by their anatomical arrangement and by neurophysiological data. Freedman and coworkers for example, recently reported that noradrenergic activation, although suppressing spontaneous firing of cerebellar Purkinje cells produced a relative enhancement of the Purkinje response to synaptic inputs from other cells (*Expl Neurol.* 55, 269; 1977). Noradrenergic projections to the forebrain contrast with the fibre pathways of classic neuroanatomy not only in the diffuseness of their distribution, but also in topographic organisation. In classically described long pathways the terminal projections of individual cells

are generally arranged so that a map of the total projection field corresponds topographically with the distribution of cell bodies. R Y Moore and coworkers have found that this sort of organisation does not occur in noradrenergic projections from the locus coeruleus to the neocortex; rather, projections from a single cell are widespread, with vast overlapping (*A. Rev. Neurosci.* in the press). Interestingly, many of the brain regions receiving noradrenergic input make reciprocal connections back to the tiny locus coeruleus nucleus. These observations suggest that the diffuse ascending aminergic systems represent a distinct category of neuronal organisation.

A neuromodulatory role is concordant with a massive literature implicating amines in various aspects of behaviour. A leading biochemical theory of schizophrenia suggests malfunction of dopaminergic systems. Alterations in mood are correlated with neuronal availability of noradrenaline. Many studies have linked catecholamines and indolamines to vigilance, reward, and learning, yet it has not been possible to identify a specific aminergic role in any of these behavioural processes. That elucidation may now be a step closer.

Egg activation

from Duncan O'Dell

WHEN an egg is fertilised, many of its properties change promptly. Most species show an increase in the rate of respiration, protein synthesis is turned on, permeability and transport characteristics of the surface membrane change, a block to the entry of supernumary sperm is established and meiosis, where appropriate, is resumed. It has long been considered that during oogenesis an egg acquires all the machinery necessary to respond rapidly to fertilisation, but that these several responses become 'blocked' until they are 'activated' by the entry of a sperm. For many years, there has been a search for the 'switch' or 'switches' that would serve to activate eggs and explain why so many different processes get turned on more or less together. This search was complicated by the fact that some eggs, such as those of sea urchins, can be parthenogenetically activated by any of a long and confusing list of treatments whereas others, such as those of sea squirts, are refractory to most procedures tried. Matters became much clearer in 1974

when Steinhardt and Epel (*Proc. natn. Acad. Sci. U.S.A.* 71, 1915) showed that the ionophore for divalent cations, A23187, would activate echinoderm eggs; subsequent work by these and other authors has shown both that many other eggs can be similarly activated and that the movement of calcium ions is intimately involved in the process.

In a more recent analysis (Johnson *et al.* *Nature* 262, 661; 1976) the activation of sea urchin eggs was divided into two stages. The first, which occurs in the minute after fertilisation or activation, involves the exocytosis of the granules under the surface of the egg leading to various surface changes and it is this event that can be brought about by the calcium ionophore. The second stage, about three or four minutes later, involves the onset of macromolecular syntheses and the most interesting feature here is that the first stage is not a prerequisite for the second. A number of treatments—ammonia, procaine, nicotine—all lead directly to the metabolic activation of the egg. Johnson *et al.* showed that all these agents caused an efflux of H^+ ions with a subsequent rise in the intracellular pH of the eggs. If this efflux

of acid was blocked in various ways, the second stage of activation did not occur. It was then suggested that low intracellular pH served as the natural 'block' of metabolism before fertilisation, with the caveat that this sort of analysis has not yet been performed on many species of egg. Johnson *et al.* concluded by speculating that such shifts of intracellular pH could be regulating mechanisms elsewhere when quiescent cells resume division.

In this issue of *Nature* (page 590) Lopo and Vacquier take up the challenge presented by this speculation. First, the observation that intracellular pH rises after fertilisation is confirmed. But the changes in pH have also been followed for much longer during development, and it has been found that the higher pH of the newly fertilised egg is not maintained for long. Since the actively dividing cells of cleavage stage embryos seem to have an intracellular pH lower than that of the 'blocked' mature egg cell, it would seem that low pH alone is no absolute barrier to the processes involved in preparing for mitosis. The initial rise in pH, then somehow serves irreversibly to 'unblock' the egg. However there may still be a link between DNA synthesis and gross intracellular pH as Lopo and Vacquier show by use of procaine. This drug promotes DNA synthesis and a high intracellular pH; when procaine is removed, both fall.

It seems established, then, that at least in sea urchin eggs an early event following fertilisation is a rise in intracellular pH and that this rise is associated with the onset of the processes of early development, but the higher pH is not necessary for the completion of these processes. Clearly, there is scope for further analysis here. All these pH measurements were made on egg homogenates and subtle local variations within the cell would have been missed. The mode of action of a drug such as procaine is by no means exactly certain. More work needs to be done before one can interpret the consequences of a rise in intracellular pH with confidence. However, the past three years, starting with Steinhardt and Epel's experiments on A23187, have taught us a great deal about fertilisation and egg activation. Although the definitive analysis is not yet quite in sight important experiments are being done and there is a feeling that an interpretation will be made. At the beginning of this century good scientists worked hard on the problem but mainly produced a baffling list of egg activating treatments, there is now hope that the scientific great-grandchildren of pioneers like J. Loeb will be able to interpret that list in terms of calcium levels, pH shifts, surface membrane changes and so on. □

Ciliar dyneins

from Roy Burns

THE similarities between the molecular basis of muscle contraction and the beating of cilia flagella have been evident for several years. Both mechanisms involve the sliding of parallel filaments, resulting from the hydrolysis of ATP by enzymes which transiently form crossbridges between the adjacent filaments: the myosin heads in the case of muscle and the dynein-containing side arms of cilia and flagella. Furthermore, the demonstration by Gibbons and Gibbons (*J. Cell Biol.* **63**, 970; 1974) that the crossbridges of sea urchin sperm flagella are frozen when the ATP concentration is suddenly lowered, resulting in rigor, strongly suggests that the dynein-ATPase crossbridge cycle resembles the Lymn-Taylor cycle of muscle (see *News and Views* **235**, 362; 1972). It is however dangerous to extend the analogy too far, and Warner, Mitchell and Perkins (*J. molec. Biol.* **114**, 367; 1977) have recently shown that the outer sidearms of cilia are structurally much more complex than the myosin head crossbridge.

Each of the outer doublets of cilia and flagella bear a pair of sidearms which tangentially approach the neighbouring doublet. These sidearms can in general be removed by dialysis against low ionic strength buffer, and the outer sidearm selectively extracted with 0.5 M KCl (Kincaid, Gibbons & Gibbons *J. supramolec. Struct.* **1**, 461; 1973), and the principal component present in such high salt extracts from sea urchin sperm tail axonemes is the high molecular weight ATPase termed dynein-A. Warner *et al.* have examined such a preparation of dynein-A from cilia from both *Tetrahymena* and the gills of the lamellibranch *Unio* by SDS-gel electrophoresis and by negative staining.

SDS-gel electrophoresis of the *Unio* gill axonemes shows two principal high molecular weight bands, present in a 2:1 ratio, and four additional components with molecular weights greater than 300,000 daltons. Extraction with high salt selectively removes approximately half of the major component (Band-3) which has an estimated molecular weight of 360,000 daltons. When the high salt supernatant from either *Unio* or *Tetrahymena* is examined by negative staining, three principal structures are observed: a 9.3 nm spherical particle with or without a centrally located accumulation

of stain, and aggregates of 2-6 of these 9.3-nm subunits. A fourth unrelated particle is occasionally observed in the *Unio* preparations with dimensions of 9.4×12.7 nm together with some solubilised tubulin and some unidentified 200×3.5 nm filaments. The 9.3-nm particle is consistent with a protein of molecular weight 348,000 daltons, and in view of the extraction conditions is considered to be the monomeric form of dynein-A.

This particle is, however, significantly smaller than the attached sidearm, which in *Tetrahymena* is hook-shaped and measures $20-22 \times 8-10$ nm (Allen *J. cell Biol.* **37**, 825; 1968). Warner *et al.* find that the outer sidearm can be resolved by negative staining into at least three morphological subunits, with a centre-to-centre spacing of 7.5 nm. What then is the relationship between these smaller subunits and the 9.3-nm extracted particles? Three possibilities are suggested; first, that the outer sidearm is composed of one or more non-enzymatic molecules with an identical molecular weight to dynein-A. This possibility should not be discounted as the resolution of SDS-gel electrophoresis is low in the high molecular weight range ($\pm 10,000$ daltons), and the high salt extraction removes only half of the Band-3 component, the remainder presumably being a different protein with the same molecular weight. The second possibility is that the sidearm is a polymer of the 9.3-nm particle. In order to account for the lower centre-to-centre spacing of the subunits of the intact arm it is necessary for a conformational change to occur during extraction, or for the subunits to be superimposed *in situ*, and indeed the sidearms are tilted towards the base at an angle of 28° from the perpendicular. The third possibility is that only the distal portion of the sidearm is extracted, the proximal part remaining attached to the outer doublets but in a form undetected by either negative staining or conventional electron microscopy. However, all of these alternatives indicate that the sidearm is much more complex than the myosin head, and support the view that although the two contractile mechanisms share certain properties, they are unrelated.

Finally, Warner *et al.* have numbered the *Unio* and *Tetrahymena* high molecular weight axonemal proteins 1-6, while Gibbons *et al.* (in *Cell Motility, Cold Spring Harbor Conferences on Cell Proliferation* (eds Goldman, Pollard & Rosenbaum) **3**, 915; 1976) had labelled the sea urchin proteins Band-C, A, D, and B, where Band-A corresponds to dynein-A (also termed dynein-1) and to Warner's

Band-3. At first sight this suggests a proliferation of cumbersome nomenclature. Two points should be made: first, Gibbons has defined the dyneins as high molecular weight (above 300,000 daltons) microtubule-associated ATPases so that certain of the sea urchin high molecular weight proteins, for example Band-B, which lack ATPase activity are not by definition dyneins. Second, it is clear that the same experimental procedure does not necessarily extract the same components from all cilia and flagella; for instance the cilia and flagella of *Aquipten* differ in their extraction properties (Linck *J. Cell Sci.* **12**, 951; 1973) and not all species of sea urchin behave identically. It is probably wise therefore to retain separate nomenclatures until the function and location of each of the high molecular weight components is clear. The differences in the extraction of different cilia and flagella suggest also that the elucidation of the structure and mechanism of movement may be hastened by exploiting obscure organisms rather than confining our attention to a single widely available species. □

Coulson rules OK

from John Walker

THE problem of calculating the electronic energy levels of defects in semiconductors has not been solved, and is currently the subject of much controversy; some new results and re-interpretations of data on point defects in diamond by Gordon Davies (*Nature* **269**, 498; 1977) strongly suggest that the method of calculation proposed by Coulson as far back as 1957 (Coulson & Kearsley *Proc. R. Soc. A* **241**, 433; 1957; see also Coulson & Larkins *J. Phys. Chem. Solids* **32**, 2245; 1971) is the most appropriate one.

Since the 1920s and the development of quantum mechanics it has been possible to calculate with reasonable (and in some cases extreme) accuracy the electronic energy levels of atoms and molecules, and hence their characteristic spectra. The calculations are simplified because an atom is an isolated system; the electrons do not interact with other atoms. Molecules are more difficult, but only a few atoms are involved, at least in the case of simple molecules.

In a solid the analogous problem to the hydrogen atom is an electron bound to a lattice defect such as a vacancy. Here the situation is complex; the surrounding lattice atoms must be taken into account, since they are

intimately connected to the defect by chemical bonds. They affect the magnitude and symmetry of the potential seen by the electron, and this influence is complicated by the fact that they can vibrate and become distorted.

In semiconductors there are simplifications in some cases—the so-called 'shallow' centres—whose energy levels lie close to the edges of the forbidden gap. These can be treated in a hydrogenic approximation. For 'deeper' levels the approximate treatment does not work, and diamond is particularly difficult because its forbidden gap is wide (which is why diamond is transparent) and all levels are deep.

On the other hand, a diamond is effectively a giant in theoretical chemistry? So why not apply to it the techniques used in theoretical chemistry? This is what Coulson and Kearsley did. They treated the neutral vacancy (a lattice site from which the carbon atom has been removed) as a 'defect molecule' containing four electrons—the 'dangling bonds' from the four nearest-neighbour carbon atoms which were broken in creating the vacancy. (For a positive or a negative vacancy there are three or five electrons.)

The calculations predicted a 1E groundstate with a 1T_2 state about 2 eV higher in energy. (E and T_2 denote doublet and triplet orbital states. The superscript $=2S+1$, where S is spin, as in atomic spectroscopy. Hence S is zero in this case.) The transition 1E to 1T_2 is allowed. It so happens that an absorption band in irradiated diamond—the GR1 band—occurs at about 2 eV and has a non-paramagnetic ($S=0$) ground state. Since irradiation produces vacancies it was reasonable to assume that this absorption band was due to the neutral vacancy. Experimental work 16 years later (Clark & Walker *Proc. R. Soc. A* **334**, 249; 1973; Davies & Pechina *Proc. R. Soc. A* **338**, 359; 1974) confirmed that the GR1 transition was indeed between an E ground state and a T excited state. So the Coulson calculations seem to work.

In his paper Davies has suggested that the calculations work equally well for the negatively-charged vacancy (V^-). He has pointed out that irradiation of some diamonds (the so-called type Ib) gives a much weaker GR1 band than normal, but produces very strong absorption in the ultraviolet—the ND1 band. Since it is unreasonable to assume that irradiation produces vacancies in some diamonds but not in others, Davies argues that they are being produced in a different charge state. Type Ib diamonds contain nitrogen, which should be a donor, so vacancies are likely to be in the

negative rather than the neutral charge state. The calculations predict that V^- probably has a 1A_2 ground state, with an allowed transition to a 1T_1 excited state several eV higher in energy. Earlier work (Davies & Lightowers *J. Phys. C: Solid State Physics* **3**, 638; 1970) has shown that ND1 is indeed due to an A to T transition and that the defect is tetrahedral, as one would expect for a vacancy. Furthermore, Dyer and Du Preez (*J. chem. Phys.* **42**, 1898; 1965) have demonstrated that ND1 is paramagnetic, which it would be with a 1A_2 ground state. They have also shown that the ND1 absorption can be strengthened, and GR1 reduced, or *vice versa*, by shining light of appropriate wavelengths on the

diamond. This phenomenon is easier to explain if ND1 and GR1 are different charge states of the same defect, rather than being different defects, as was formerly assumed.

Davies's suggestions therefore fit the facts. They indicate that further work is desirable on the ND1 centre in EPR. They imply that the sign of charge carriers involved in photoconductivity at ND1 and GR1 should differ, which can be checked. And most important of all, they imply that the 'defect molecule' approach of Coulson and his coworkers is the best way to calculate the electronic properties of defects in semiconductors. It is to be hoped that Davies's work will stimulate further activity amongst the theoreticians. □

Primaeval heavy leptons

from P. C. W. Davies

DISCOVERIES in subatomic particle physics take place against a continual struggle for more technology and money. The Universe enjoys complete freedom from these worries and produces for free events which may tax human resources to the limit. During the big bang, exceedingly high temperatures and energies stimulated subatomic processes of all varieties, some of which have left relics for us to observe today, so it has become increasingly attractive to confront the theoretical work on these processes with astrophysical and cosmological, as well as technological, data.

A famous example of this approach concerns the unknown rest mass of the neutrino, which most physicists would like to be zero. Laboratory experiments are not particularly sensitive to the neutrino mass, but cosmology is. A study of the fireball resulting from the big bang indicates that the entire Universe should be filled with primaeval neutrinos, about three hundred of them per cm^3 —a billion times more numerous than atoms. The existence of a similar background of photons was confirmed by observation in 1965, but neutrinos interact so weakly with matter (it would take a lump of lead several thousand light years thick to absorb them) that their presence has remained undetected. Nevertheless, their energy will gravitate like any other, and thereby influence the characteristics of the expanding Universe. If they do possess even a tiny rest mass, they are present in such profusion that the cumulative gravity of all the

neutrinos could dominate the cosmological motion. It has been estimated that a neutrino mass in excess of 40 eV (about 10^{-4} of the electron mass) would be sufficient to cause the expansion of the Universe to decelerate more rapidly than observations permit, and eventually to bring about its demise by gravitational collapse.

In two recent papers in *Physical Review Letters*, similar arguments have been used to place mass limits on a hypothetical new particle: a neutral heavy lepton. This entity is predicted by some recent gauge theories of weak interactions and is being actively sought by particle physicists. Its properties would be rather like those of a super-heavy neutrino. If these particles exist, they would have been present along with their antiparticles in the primaeval fireball, but their high mass would have greatly reduced their abundance over that of ordinary neutrinos. In the first paper, the late Benjamin Lee of Fermilab, and Steven Weinberg of Harvard University (currently on leave at Stanford) consider the thermal equilibrium abundance of the heavy leptons when the temperature of the Universe was about 10^{10} K (about one second after the big bang). Before this point the cosmic matter density was so high that even the feebly-interacting neutrinos would have felt its presence and been held in thermal equilibrium with it. This fact enables the abundance of neutrinos and other particles to be calculated from the common temperature of all the primordial material. However, when it comes to calculating the abundance of the heavy leptons, it turns out that their density would have been so low that their natural incli-

A hundred years ago

THE GELADA.—Several living specimens of this extremely rare Abyssinian monkey first described by Dr Ruppell in 1835, have quite recently reached this country for the first time and are being exhibited at the Alexandra Park. The exact affinities of the species have never been fully determined, different biologists placing it, some with the Macaques, others with the Baboons. It is peculiar in that the male is covered with very lengthy hair like that of the Wanderoo, whilst the female is a much more ordinary-looking monkey. In the male, also, there is a bare spot, in shape like an inverted T, upon the breast which is of a light-pink colour, becoming red and expanded into an inverted heart-shaped patch upon excitement. The tail is long and like that of a lion, having a bushy tuft at the extremity. The colour is a sooty dark-grey brown, verging upon black; the hands and face are black; the nails are powerful and long. The size of the male is about that of a Chimpanzee four years old. The eyes are close together, and the snout prolonged. The living animal has a habit of everting the whole upper lip when irritated and thus exposing its formidable array of teeth.

From *Nature* 16, 11 October, 512; 1876.

nation to annihilate with their antiparticles was inhibited, simply due to the rarity of particle-antiparticle encounters. Consequently, relatively more of them would have escaped this fate and survived to populate the Universe. Using a simple model of the primaeval fireball, Lee and Weinberg are able to show that the mass of these heavies must be at least about 2 GeV (four thousand times the mass of the electron) to avoid the gravity of this residue drastically decelerating the Universe. Curiously, the same argument which places an upper bound on the neutrino mass places a lower bound on the heavy lepton mass. The reason for this is that the heavier the particles the more they gravitate individually, but the less abundantly they are produced at a given fireball temperature. Because of these competing effects, the combined gravity of all the particles is greater if either the mass is especially low or high—very many light particles or a few very heavy ones. In the neutrino case, we know from laboratory experiments that the mass is tiny, so the individual-gravity factor dominates,

but the reverse is true of the heavy lepton, and it is the abundance factor which is more important.

A fascinating consequence of this calculation is that the abundance of these particles, if they exist and are not too massive, could still be high enough to contain nearly all the mass of the Universe, which opens up the prospect of dozens of times more matter in the form of weakly interacting, virtually unobservable, heavy neutrinos than in all the galaxies. If this is correct, then it might indeed be sufficient to cause the cosmological expansion eventually to reverse into collapse.

In the second paper, Duane Dicus and Edward Kolb of the University of Texas at Austin, and Vigdor Teplitz of the Virginia Polytechnic Institute consider how the Lee-Weinberg result would be modified if the heavy neutrinos are weakly unstable, and decay after a while into ordinary neutrinos. The essence of their calculation is the observation that cosmic neutrinos resulting from recent heavy lepton decays are more energetic, and hence gravitate more strongly, than the primordial ones, because the latter have been redshifted to low energies by the expansion ever since the big bang. Hence the cosmological measurements provide a limit on the lifetime of the lepton. However, this quantity

can also be inferred from the theory of weak interactions if the mass of the lepton is known. Turning the argument round, the lifetime limit can be used to place an upper bound on the mass, which works out at about 10 MeV, or less than one hundredth of the Lee-Weinberg value for a stable heavy lepton. The particle lifetime corresponding to this is about a year.

The authors have checked that any high energy photons also produced in the decay events during the first few hundred million years would have been degraded (thermalised) by scattering. Those produced after this would be swamped by the cosmic X-ray background, so are not detectable. Nor do the energetic decay neutrinos affect the nucleosynthesis in the primaeval fireball, because at 200 s this process occurs too early for the decay products to have accumulated significantly. Unfortunately, the presence of the decay neutrinos, in spite of their higher energy, is still too ephemeral to register in neutrino detectors or noticeably to affect protons in cosmic rays so that, intriguing though these ideas are, no positive experimental verification of cosmic heavy leptons appears likely. Nevertheless, the imposition of mass bounds at least lets the laboratory physicist know what to expect from terrestrial ones. □

What future for Antarctic geology?

from Peter Barker

The 3rd Symposium on Antarctic Geology and Geophysics held at Madison, Wisconsin, on 22–27 August, was cosponsored by SCAR, IUGS and ICG. The organising committees, chaired by Campbell Craddock (University of Wisconsin-Madison), ensured a friendly and interesting meeting.

ANTARCTIC Earth science can be a slow, difficult business, at sea as well as on land. The weather is often foul and the ratio of outcrop to ice vanishingly small. The great expense of putting a party into the field can generate years of delay, and tends particularly to discourage the return visit which a mature assessment of the first season's work often recommends. Along with delay, these conditions breed unconscious error, over-reached speculation and a parochial viewpoint, and ensure their prolonged survival in the literature. Nevertheless, the past few years have seen a revolution in the earth sciences generally, and considerable

funds allocated for Antarctic research. The importance of the symposium at Madison, therefore, lay not in its being larger, better attended and broader in scope than its predecessors at Oslo (1970) and Cape Town (1963), but in the opportunity it provided to assess the quality and global relevance of contemporary Antarctic earth science, and consider its future.

Continental geology, the traditional core topic, occupied less of the programme and produced few of the kind of surprises which must have animated past meetings: the heroic age of exploration and reconnaissance mapping is past, the emphasis shifted towards re-mapping anomalous areas and questioning the reality of the classically-defined widespread orogenic episodes (in North Victoria Land, for example). Better descriptions of the oldest Antarctic rocks and more confident (although conflicting) comparisons with neighbouring Gondwana continents

Peter Barker works in the Department of Geological Sciences, University of Birmingham.

were evident than at Oslo, but for most of Antarctica the isolated coastal exposures and ice-covered interior seem a crucial impediment to further understanding. Radar ice-thickness measurements are revealing something of sub-ice morphology and, in those rare cases where allied geophysical data are available, seem capable of generating some small, speculative understanding of the interior. There is no doubt, however, that the geology of most of Antarctica, East and West, and its important glacial history, will remain obscure without an expensive and time-consuming programme of survey-controlled, regional sub-ice drilling.

Perhaps the liveliest part of the symposium, in contrast, was a two-day section on the geodynamics of the Scotia Arc. Considerable progress has been made since 1970, particularly in understanding southern South America's evolution and strengthening its connection with South Georgia. A Cretaceous age for almost all the Scotia Sea is now established, but the earlier history of the region remains uncertain. A crucial unknown, the positions of the Antarctic Peninsula and South America at the Gondwanaland margin, should emerge shortly; magnetic anomaly-based Gondwanaland reconstructions at Madison were conflicting, but obviously convergent, and the growth of marine geophysical interest in the Weddell Sea should complete the puzzle.

Under the influence of geodynamics, some Scotia Arc studies are oriented towards the processes involved in formation. The area is particularly well-endowed with back-arc basins, and a geochemical data base for these and other active margin igneous processes as broad as any in the world is now available.

Mineral resources, presently occupying the attention of Antarctic Treaty signatories were considered in only six out of about 150 papers. This dearth does not reflect wilful ignorance (the academic ostrich!), nor in the informal opinion of the meeting does it hide a much greater actual knowledge. Simply, reconnaissance mapping is complete and any resource detectable by such means is known; none is economic to extract at present, and such more detailed, follow-up surveys as have been carried out have proved no more fruitful. Offshore petroleum prospects were not discussed at Madison but this case is essentially similar, although there has been less reconnaissance.

The main goal of Southern Ocean marine geology (a topic hardly considered at Oslo) is an understanding of the interdependence of climate, circulation, sedimentation and Antarctic

Have gunk, will travel

from Peter J. Smith

A *nuée ardente* is a rapidly flowing, turbulent and often incandescent cloud of gas and ash originating in an explosive volcanic eruption. The first one to come to the attention of scientists, but surely not the first ever to be seen, was that from Mt Pelée (Martinique), which in 1902 overwhelmed the town of St Pierre, killing all but two of the inhabitants. This still remains the most famous of all, although many others, including much larger ones, have been observed since, not least from Mt Pelée itself.

But observation is one thing and scientific investigation is another; by their very nature *nuées ardentes* in action (as opposed to the deposits they leave behind) are not particularly amenable to the latter. The pioneer in this field was Frank Perret, who studied hundreds of *nuées ardentes* at close quarters after the eruption of Mt Pelée in 1929, captured their visual beauty in a remarkable series of photographs, and almost ended as a victim of one. Today, however, some aspects of glowing clouds may be studied from the relative safety of an aeroplane, which is how Moore and Melson (*Bull. Volcan.* **33**, 100; 1969) observed the 1968 eruption of Mt Mayon (Philippines) and how Stith *et al.* (*Geophys. Res. Lett.* **4**, 259; 1977) approached the eruption of St Augustine Volcano (Alaska) in 1976.

One of the most conspicuous characteristics of a *nuée ardente* is, of course, its speed, which reference books usually give as "perhaps 100 kilometres an hour" or something equally vague but which Stith and his colleagues have now determined much more accurately using aerial photography. Thus the *nuée ardente* produced by St Augustine Volcano on 8 February 1976 began moving down the initial 1:3 slope with a speed of 180 km per hour, slowed to 75.6 km per hour down the subsequent 1:7 gradient, then to 46.8 km per hour (1:12) and finally to 21.6 km per hour (1:28) before entering the sea 6 km from the volcanic cone. The average speed was 54.0 km per hour, which means that the 6 km was covered in less than 6.7 minutes.

The chief reason for such astonishing speeds is the 'fluidisation' of the volcanic particles brought about by the release of gases, a process which greatly reduces the frictional resistance of the mass as it moves under gravity. The dangers are obvious. A *nuée ardente* travels not only rapidly but with very little noise. A community in its path may be overcome without ever knowing what happened. □

Peter J. Smith is a Reader in the Department of Earth Sciences at the Open University.

glaciation in a ocean basin of changing shape and with the most vigorous oceanic current system in the world. At Madison, papers based mainly on Deep Sea Drilling data and the Eltanin piston core collection attempted partial analyses of some of these relationships over time intervals varying from 1,000 years to 150 Ma. Individual papers were interesting but the pervading impression was of a huge field largely unexplored, with the gaps between contributions at least as important.

The four disparate fields considered above, with very few exceptions, contain all that is of wider interest in Antarctic earth science at present. They are at very different stages of development, from youth to old age, and their futures too are likely to diverge. Marine geology should prosper independently, with the driving force of the Southern Ocean's importance to world climate and primary productivity, and the basic unity of circum-Antarctic circulation as a constraint on the multi-disciplinary approach. One looks, perhaps, for an

injection of numerical modelling, to link through the huge range of periodicities being examined and to direct further sampling.

The future of Antarctic geology is less certain. Some aspects, such as Scotia Arc studies, may continue to develop and, as the emphasis in geology changes, remain as fertile ground for the study of processes. For much of Antarctica, however, a similar transition from unmapped wilderness to geological laboratory may not be possible; without sub-ice drilling too little of the context may ever be learnt. The value of Antarctica to global geology will then decline. Economic geology has reached a similar impasse. Workable deposits within and around Antarctica must exist and, given the increasing world pressure on known resources, continued interest is inevitable. There are no easy, short-term prospects, however, so the opportunity is still there for a balanced, disinterested political decision on the course of further exploration and exploitation. □

Upper limits on the Faraday rotation in variable radio sources

J. F. C. Wardle

Department of Physics, Brandeis University, Waltham, Massachusetts 02154

Data on the linear polarisation of variable radio sources are examined for evidence of a variable component of Faraday rotation. Strong upper limits are set, and these are shown to have profound implications for the physics of these sources. It is suggested that the electron energy spectrum is a relativistic Maxwellian rather than a power law. This may be consistent with the relativistic blast wave models of Blandford and McKee.

COMPACT radio sources which contain appreciable quantities of non-relativistic electrons will exhibit Faraday rotation and Faraday depolarisation at long wavelengths. The rotation at a frequency ν is

$$\chi = \frac{e^3}{2\pi m^2 c^2} \frac{n_c H \cos\theta}{\nu^2} l \text{ rad} \quad (1)$$

where n_c is the density of cold electrons, H is the magnetic field which makes an angle θ with the line of sight, and l is the thickness of the source along the line of sight. When $\chi \sim$ a few radians, the degree of linear polarisation drops to a small value¹.

If a radio source expands conserving magnetic flux, then $\chi \propto$ radius⁻⁴. Thus a variable radio source may exhibit variable Faraday rotation. If observations are made at two or more frequencies then changes in Faraday rotation can in principle be separated from changes in the intrinsic angle of polarisation. In this way, upper limits on the observed Faraday rotation can be used to place stringent upper limits on the density of cold electrons in compact radio sources.

The results of four years of monitoring the flux density and linear polarisation of 82 compact extragalactic radio sources were reported by Altschuler and Wardle², and an analysis of the data was given by Altschuler and Wardle³. Thirty-two of the sources showed distinct variability in their polarisation. Since the observations were made at two frequencies (8,085 MHz and 2,695 MHz), the data can be examined for the presence of Faraday rotation.

An appreciable variable component of polarisation was observed in many sources at 2,695 MHz, suggesting that Faraday rotation is often not large at this frequency. We have used this to derive a crude upper limit on the cold electron density³, and we found that the ratio of the densities of relativistic to cold electrons was typically in the range $n_{rel}/n_c \sim 10^{4 \pm 4}$.

Here the data are examined more carefully and the limits on the density of cold electrons are improved by an order of magnitude. This is shown to have profound implications for the physics of compact radio sources. The data suggest that the energy spectrum of the radiating electrons may be a relativistic Maxwellian rather than a power law. Almost identical conclusions have been reached independently by Jones and O'Dell⁴.

The observational data

In practice it is not a trivial task to isolate effects due to Faraday rotation from the data. There are several reasons for this: the variations in polarisation are rapid and intricate and are often poorly correlated between the two frequencies; there are few well defined simple outbursts; and, perhaps most important, the variable component is superimposed (vectorially) on a constant or slowly varying component of comparable amplitude (see refs 2 and 3).

We cannot determine the polarisation of the underlying component with much confidence in any case, so a simple statistical approach will be used. Of the 32 sources (from ref. 2) that exhibit variable polarisation, 16 are clearly variable in the degree of polarisation at both frequencies. In four cases the variations are distinctly uncorrelated between the two frequencies, and these sources have been dropped from the sample. For the remaining 12 sources the fluctuations in the degree of polarisation are fairly large and reasonably similar at both 8,085 MHz and 2,695 MHz, suggesting that the sources are optically thin much of the time, and that we are looking at the same piece of the source at both frequencies. The 12 sources have been selected without regard to the behaviour of the position angle of polarisation or the total flux density.

0851+20 (OJ287) is particularly important. In March 1974, the polarisation jumped at both frequencies from less than 2.5% to over 12%. Here the source is undoubtedly optically thin. Also, the variable component is so strongly polarised that the effect of any underlying constant component is very small.

If there is an appreciable variable component of Faraday rotation in these sources, we would expect to see changes in the position angle of polarisation at 8,085 MHz that are echoed at 2,695 MHz with an amplitude nine times larger. Inspection of the data in ref. 2 reveals no obvious cases of such behaviour. Usually the observed changes in position angle are either quite well correlated between the two frequencies, or else they are larger at the higher frequency.

Rough upper limits on the amount of Faraday rotation can be placed in the following way. For each day's observations, we take the difference between the position angles at the two frequencies, that is $\Delta\chi = \chi_{2,695} - \chi_{8,085}$. We then compute the mean and standard deviation of $\Delta\chi$ for all the observations of each source. (For 0851+20, we have used only the data between March 1974 and June 1975). The mean, $\langle\Delta\chi\rangle$, represents a constant component of Faraday rotation. This may be attributed to Faraday rotation both in our own Galaxy, and in whatever structure surrounds the variable radio source. The standard deviation, $\sigma\Delta\chi \times 9/8$, is a rough upper limit on the r.m.s. Faraday rotation at 2,695 MHz inside the variable component.

Two corrections should be made to this estimate. First, the average errors in the position angle measurements, $\langle\epsilon_{8,085}\rangle$

and $\langle \epsilon_{2,595} \rangle$, should be subtracted quadratically. Second, the effect of superimposing the polarisation of a constant component is to reduce the observed changes in position angle. This can be compensated for, to first order, by multiplying $\sigma_{\Delta\chi}$ by a factor $(\bar{m} + m_v)/m_v$, where \bar{m} is the average degree of polarisation of the source, and m_v is the r.m.s. amplitude of the variable component, both at 2,695 MHz. The upper limit on the r.m.s. variable Faraday rotation at 2,695 MHz is then:

$$\sigma'_{\Delta\chi} = \frac{9}{8} \left(\frac{\bar{m} + m_v}{m_v} \right)_{2,695 \text{ MHz}} (\sigma_{\Delta\chi}^2 - \langle \epsilon_{8,085} \rangle^2 - \langle \epsilon_{2,695} \rangle^2)^{1/2} \quad (2)$$

The results are presented in Table 1 for the 12 sources in our sample.

It can be seen that in most cases $\sigma'_{\Delta\chi}$ is of the order of half a radian, and in two cases is considerably less. These are, however, probably gross overestimates of the typical variable component of Faraday rotation in these sources. First, in each case (except 0851+20) we have used all the data, averaging over several outbursts. Presumably at certain times the sources may be opaque, leading to fluctuations in position angle that are not correlated at the two frequencies. Second, where there is limited data, or the variable component of polarisation has a large amplitude, then the amplitude of the underlying component may be badly overestimated, and hence too large a correction is applied to the observed values of $\sigma_{\Delta\chi}$ in column (3). Third, in five out of the seven cases where $\sigma_{\Delta\chi}$ is greater than 10° , inspection of the data shows that it is the position angle at the higher frequency that is showing rapid fluctuations, and is, therefore, unlikely to be due to Faraday rotation. In support of the first two points, for 0851+20 where it is certain that the source is optically thin, and where the effect of an underlying constant component is very small, we find $\sigma'_{\Delta\chi} \lesssim 1/8$ radian.

We have found no evidence for variable Faraday rotation in these sources. From the above discussion, the typical amount of variable rotation at 2,695 MHz is most unlikely to be more than a few tenths of a radian. In the calculations that follow, however, we shall use the conservative upper limit of 0.5 radians.

Calculations

The Faraday rotation by cold electrons of density n_c is given by equation (1). The density of relativistic electrons can be estimated from the optically thin flux density. The emission coefficient for synchrotron radiation is given by⁵

$$\epsilon_v = c_5(p)N_0(H \sin\theta)^{(p+1)/2} \left(\frac{v}{2c_1} \right)^{(1-p)/2} \quad (3)$$

where the electron energy spectrum is of the form

$$N(E) dE = N_0 E^{-p} dE, \quad E_1 < E < E_2 \quad (4)$$

The optically thin brightness temperature is

$$T_b = \frac{c^2}{2k\nu^2} \epsilon_\nu l \quad (5)$$

The number density of relativistic electrons is

$$n_{rel} = \int_{E_1}^{E_2} N(E) dE = \frac{N_0}{p-1} (\gamma_1 mc^2)^{1-p} \left[1 - \left(\frac{\gamma_2}{\gamma_1} \right)^{1-p} \right] \quad (6)$$

where $\gamma = E/mc^2$.

Combining these we obtain

Table 1 The observed limits on Faraday rotation, at 2,695 HMz in 12 variable radio sources

Source	$(\Delta\chi)$ ($^\circ$)	$\sigma_{\Delta\chi}$ ($^\circ$)	$\sigma'_{\Delta\chi}$ ($^\circ$)
0300+47	15	3	<15
0605-08	64	13	39
0735+17	5	7	<22
0851+20	23	6	8
1055+01	-42	7	35
1334-12	-50	19	45
1510-08	-7	16	39
1641+39	26	12	81
1749+09	35	34	49
1921-29	-5	7	25
2155-15	21	13	32
2200+42	67	27	33

$$\frac{n_{rel}}{n_c} = \frac{4c_1}{c_5} mce^2 \frac{3-(p+1)/2}{p-1} \frac{kT_b}{\chi \tan\theta} \left(\frac{v}{v_{B1}} \right)^{(p-1)/2} \times \gamma_1^{1-p} \left[1 - \left(\frac{\gamma_2}{\gamma_1} \right)^{1-p} \right] \quad (7)$$

$$\text{where } v_{B1} = \frac{eH}{2\pi mc} \sin\theta.$$

A lower limit on n_{rel}/n_c is obtained by setting $v = \gamma_1^2 v_{B1}$. If $p > 1$, we allow $\gamma_2 \rightarrow \infty$ for simplicity then

$$\frac{n_{rel}}{n_c} \geq \frac{T_b}{\chi \tan\theta} \times \begin{cases} 1.5 \times 10^{-10} \ln \gamma_2/\gamma_1, & \text{if } p = 1.0 \\ 4.9 \times 10^{-10} & p = 1.5 \\ 3.1 \times 10^{-10} & p = 2.0 \end{cases} \quad (8)$$

T_b is typically observed⁶ to be in the range 10^{11} – 10^{12} K. In the previous section we derived upper limits on χ of a few tenths of a radian at 2,695 MHz. Hence for all sources that show variable polarisation at 2,695 MHz, we find $n_{rel} \gg n_c$.

This limit is independent of the magnetic field strength and the source dimensions. This is important since it makes the argument independent of the distance to the source, and also independent of the path length through the source, which may not be observable for example in the case of a thin shell geometry.

Lower limit on the relativistic electron energy spectrum

The limits we have derived on the density of cold electrons are so severe that we must also consider Faraday rotation by the relativistic electrons themselves. This is dominated by the lowest energy electrons and therefore can lead to limits on the presence of low energy relativistic electrons. Faraday rotation by an electron with a Lorentz factor γ is roughly proportional to γ^{-2} . (This is easily understood since in the rest frame of the electron, the radio photon is increased in frequency by a factor $\sim \gamma$.) For a power law electron energy spectrum, the equivalent density of cold electrons is^{4,7}

$$n_c(\text{equ}) = \frac{(p-1)(p+2)}{(p+1)} n_{rel} \frac{\ln \gamma_1}{\gamma_1^2} \quad (9)$$

where γ_1 is the low energy cut off in the electron energy spectrum. Combining (9) with equations (1), (3) and (5) we find

$$\chi = A(p) \frac{\ln \gamma_1}{\gamma_1^2} \left(\frac{\gamma_1}{\gamma_2} \right)^{p-1} kT_b \cot\theta \quad (10)$$

where

$$A(p) = \frac{(p+2)3^{(1-p)/2}e^3}{(p+1)c_6(p)\pi m^2 c^4}$$

If the source becomes optically thick at a frequency close to 2,695 MHz, then $\gamma \sim \gamma_n \sim 10^{-9} T_b$ (ref. 8). Setting $\chi < \frac{1}{2}$ and $\theta = 45^\circ$, we obtain the limits on γ_i listed in Table 2.

Since these are strong lower limits on γ_i , it is clear that the electron energy spectrum falls off rapidly at energies not far below the energy of the electrons radiating at 2,695 MHz. This requires that the acceleration mechanism produces copious electrons with Lorentz factors between 100 and 1,000, but few with Lorentz factors much below 100. This will be discussed later.

Average energy per nucleon

An important parameter for the dynamics of variable sources is the average energy per nucleon, $\Gamma m_H c^2$, where m_H is the mass of the hydrogen atom. A lower limit on Γ occurs when there is no non-relativistic plasma present. In this case

$$\Gamma = \frac{(1+k) \int_{E_i}^{E_j} EN(E) dE}{n_{rel} m_H c^2} \quad (11)$$

where k is the ratio of the energy in the protons to the energy in the electrons. Values of k in the literature range from 0 to $m_H/m \sim 1,836$ depending on the acceleration mechanism under consideration. As an example, with a power law energy spectrum with $p = 1$, and using the limits on γ_i and γ_j in Table 2,

$$\Gamma = (1+k) \frac{m}{m_H} \cdot \frac{\gamma_j}{\ln(\gamma_i/\gamma_j)} \sim 0.2(1+k) \frac{\gamma_j}{\gamma} \left(\frac{T_b}{10^{12}} \right) \quad (12)$$

Hence, unless $k < 5$ and $\gamma_j < 5\gamma$, $\Gamma > 1$ and the material inside a variable radio source is highly relativistic. For larger values of p the conditions are less stringent, but it seems likely that, in general, variable radio sources may contain purely relativistic plasma and that the internal sound speed is close to $c/3$.

This result can be used to argue against certain simple models of variable radio sources based on non-cosmological redshifts. In attempting to understand the apparent 'faster than light' expansion of some sources observed using VLBI techniques, it is sometimes suggested that the radio sources may be closer than is indicated by their redshifts⁹. The double sources that are observed would then be separating at velocities comfortably less than the speed of light, and might simply be similar to the well known giant double radio sources, but on a very much smaller scale.

The results found here, however, are independent of the distance to the sources. If each radio component of a double source expands freely, it will do so at about its internal sound speed, which we have shown to be very probably close to the speed of light. If the two components are separating more slowly than this then they will merge together, and a double source will not be seen at all.

Therefore, as in the case of the giant double radio sources, it is necessary to restrict the velocity of expansion to less than the velocity of separation. There are two obvious ways of doing this. First, one might add non-relativistic matter to reduce the internal sound speed. From the arguments already presented, this can be ruled out. Second, the components may be confined by the ram pressure of the external medium¹⁰. This requires $\rho_{ext} v^2 \sim$ internal energy density $\sim \Gamma c^2 \rho_{int}$, where ρ_{ext} and ρ_{int} are the external and internal densities, and v is the velocity of the component through the surrounding medium. But in this model, $\rho_{ext}/\rho_{int} \sim$ component size/component separation < 1 . Hence we require $v^2 > \Gamma c^2$, which contradicts the original assumption that the motion is non-relativistic.

Table 2 Lower limits on the low energy cut off, γ_i , of the electron energy spectrum

T_b (K)	p	γ_n	γ_i	γ_n/γ_i
10^{12}	1.0	1,000	> 41	< 24
	1.5	1,000	> 100	< 10
	2.0	1,000	> 161	< 6
10^{11}	1.0	100	> 10	< 10
	1.5	100	> 21	< 5
	2.0	100	> 30	< 4

More complicated schemes could doubtless be constructed, but the internal energy densities in these sources are enormous, regardless of their distance. It is, therefore, not very surprising if relativistic motions are observed. If the sources are at smaller distances than indicated by their redshifts, so that the measured motions are non-relativistic, then there may be severe difficulties in constructing models that are consistent with the observed limits on Faraday rotation.

Discussion

We have used the observed limits on Faraday rotation in variable radio sources to argue that (1) the density of any cold electrons present is very much less than the density of relativistic electrons; (2) the energy spectrum of the relativistic electrons cuts off rapidly at Lorentz factors not far below 100, and (3) the average energy per nucleon may well be $> m_H c^2$.

Further information concerning the electron energy spectrum can be obtained from the radio spectra of the outbursts. The rapid rate of decay of individual outbursts, and the relative rates of decay observed simultaneously at 2,695 and 8,085 MHz suggests that the radio spectrum steepens with time³. This would be consistent with a high-energy break in the electron energy spectrum that sweeps through the radio window as the source expands. More direct evidence is given by Andrew *et al.*¹¹ in the case of the giant 1968–69 outburst of 3C354.3. Here the spectrum of the outburst itself can be followed with some confidence, and again it is found that at late times the spectrum steepens drastically.

This high-energy cut off may be caused by radiation losses or may be intrinsic to the electron energy spectrum. But in any case, it seems that the electron energy spectrum is relatively narrow, extending neither to very high energies nor to very low energies. This is an important clue to the nature of the acceleration mechanism.

One possible spectrum of this type is a relativistic Maxwellian, of the form

$$N(E) dE = N_0 E^2 e^{-E/kt} dE \quad (13)$$

Formulae for computing the radiation from a relativistic Maxwellian distribution are given by Pacholczyk⁵. Such a distribution can arise naturally in a plasma at very high temperatures which is in thermodynamic equilibrium. The observed brightness temperatures suggest that plasma temperatures of the order of 10^{12} K are required.

One way of attaining such a high temperature has been discussed in some detail by Blandford and McKee¹². This involves a very high energy shock wave propagating through a thermal plasma at relativistic velocities. The jump conditions imply that in a co-moving frame just behind the shock, the mean Lorentz factor of the nucleons, $\Gamma \sim$ shock Lorentz factor. If the VLBI observations are interpreted in terms of relativistic kinematic effects¹³, then Γ is typically in the range of 1 to 10. If a fraction ϵ of the energy of the shocked particles goes into the electrons, then the electron temperature is

$$T \sim \frac{\epsilon \Gamma m_H c^2}{3k} \sim 3.6 \times 10^{12} \epsilon \Gamma \quad (14)$$

The appropriate value of ϵ is extremely uncertain, but if it is not too small, then electron temperatures of the order of 10^{12} K

can be achieved, and the electron energy spectrum may be close to a relativistic Maxwellian. If at any time the electron temperature is much greater than 10^{12} K, then 'inverse Compton cooling' can rapidly pull the temperature down to 10^{12} K again¹⁴. The radiation from a relativistic blast wave is discussed by Blandford and McKee¹⁵, who consider both power law and relativistic Maxwellian electron energy spectra.

The amount of Faraday rotation expected from a relativistic Maxwellian distribution can be computed easily; from Sazonov (1969), the equivalent density of cold electrons is

$$n_c = - \int_0^\infty \gamma \ln \gamma \frac{\delta}{\delta_\gamma} \left[\frac{1}{\gamma^2} N(\gamma) \right] d\gamma \quad (15)$$

Inserting equation (13), and writing $\gamma_0 = \frac{kT}{mc^2}$

$$n_c \sim \frac{n_{rel}}{2\gamma_0^2} (\ln \gamma_0 + 1 - \xi) \quad (16)$$

where ξ is Euler's constant, and $\gamma_0 \gg 1$.

If we are observing in the optically thin part of the spectrum, but below the peak, that is $\gamma = (v/v_B)^{1/2} < \gamma_0$, then we find

$$\chi = \frac{9.3^{1/3}}{4\pi} \left(\frac{\gamma}{\gamma_0} \right)^{-2/3} \frac{(\ln \gamma_0 + 1 - \xi)}{\gamma_0} \frac{T_b}{T} \cot \theta \quad (17)$$

$$\approx \frac{1}{\gamma_0} \ll 1 \text{ if } T \sim T_b \sim 10^{12} \text{ K}$$

Conclusions

We have shown that the observed lack of Faraday rotation in variable radio sources places severe restriction on the density

of both thermal plasma and low energy relativistic electrons. The fact that $n_{rel}/n_c \gg 1$ can be taken as direct evidence against all models in which the electrons are accelerated by betatron and Fermi processes in a turbulent plasma¹⁶.

It is also clear that the relativistic electron energy distribution does not extend to very low energies. There is weaker evidence from the radio spectra that the distribution does not extend to very high energies either, and may in fact be relatively narrow.

One possible distribution function of this form is a relativistic Maxwellian, such as may be produced behind a relativistic blast wave¹⁸. This automatically gives negligible internal Faraday rotation and if the VLBI observations are interpreted as relativistic kinematic effects, naturally leads to brightness temperatures of 10^{11} – 10^{12} K. The amount of internal Faraday rotation implied by equation (17) is so small, that it may be necessary to consider the decreasing Faraday rotation external to the shock, caused by sweeping up the ambient medium. In some situations this can produce the dominant contribution to $\Delta\chi$.

In a future paper we shall show that relativistic blast wave models can account for several other features of the spectra, flux variations and polarisation of variable radio sources.

Uranium anomaly in Black Sea sediments

Egon T. Degens, Francis Khoo & Walter Michaelis

Geologisch-Paläontologisches Institut der Universität Hamburg, Bundesstrasse 55, 2000 Hamburg 13, West Germany

The upper 90 cm of Black Sea basin sediment with an areal extension of $2.96 \times 10^5 \text{ km}^2$ has an U_3O_8 content of 6.7×10^6 tonnes. Plankton is the prime agent for uranium fixation. Reducing conditions at depth permit uranium to accumulate over the past 5,000 yr. Energetically self-sufficient burning of the top 1-m strata will lead to U_3O_8 concentrations in the order of 100 g per tonne ash.

THE Black Sea is the largest anaerobic water body in the world ocean and measures almost half a million km^3 (ref. 1). Its present environmental state is a consequence of Holocene sea-level rise and associated formation of a stable pycnocline restricting free exchange of molecular oxygen to the deep water². Holocene sediment cores from the euxine abyssal plain show, almost in slow motion, the development from a fully oxygenated fresh water 'Black Lake' to the modern brackish-marine Black Sea³. A typical 1 m sediment section consists from top to bottom of: coccolith ooze, sapropel, and light lutite. The sapropel-lutite boundary, with an assigned age of about 5,000 yr BP

marks the event when the Black Sea became permanently stratified and euxinic conditions established at the sediment-water interface⁴.

Fluctuations in redox potential may cause depletion or enrichment in certain elements both for water and sediment. Here we report on the mechanism of uranium concentration in Black Sea sediment as a function of a changing habitat.

Samples and analytical procedures

The uranium content in abyssal Black Sea mud is almost one order of magnitude larger than in average marine sediment^{5, 6}. Similar concentrations are known from sediments of Norwegian fjords and the Baltic Sea^{7, 8}. It seems, therefore, that restricted environments with a trend to euxinic conditions favour accumulation of uranium.

In the Black Sea abyssal mud the U_3O_8 concentration rarely exceeds 50 p.p.m. and 25 p.p.m. can be taken as a representative mean value. In spite of the high uranium level and the wide areal distribution, the anomaly seems to be, on first sight, of no economic significance. This outlook, however, may change by closer examination of the deposit from a sedimentological and geochemical point of view. This is because the high content

Fig. 1 Bathymetric chart of Black Sea and location of stations.

of organic matter and carbonate may allow for a considerable reduction in sediment mass by burning; furthermore, the material is unconsolidated and thixotropic.

Water and sediment were collected during RV Chain cruise of the Woods Hole Oceanographic Institution in Spring 1975. Location of stations is shown in Fig. 1. The sample collection has been supplemented with Pleistocene sediments obtained during the deep-sea drilling operation of Glomar Challenger, Leg 42 in the Black Sea in May–June 1975 (Fig. 1).

Uranium determinations were carried out spectrophotometrically using methods previously developed^{9,10}. Principally, uranium was extracted with tri-*n*-octylphosphine oxide (TOPO); and 2-(5-bromo-2-pyridylazo)-5-diethyl-aminophenol (bromo-PADAP) was used as a chromogenic reagent. Uranium nitrate was used as spike and syenite rock SY-2 and SY-3 from Canadian certified reference materials project, Mines Branch, Ottawa, were used for intercalibration.

Results

The three stratigraphic units—coccolith, sapropel and lutite—can be distinguished by their carbonate and organic matter content (Table 1). The core section is close to Station 379 (Fig. 1). The carbonate fraction in the lutite unit is principally composed of reworked Cretaceous and Tertiary coccoliths, whereas in the sapropel and coccolith units it is authigenic. The organic matter in the sapropel is principally land-derived, particularly at the base of the unit. Increase in carbonate content towards the top signals a progressively higher input of marine planktonic material.

The U_3O_8 content in the sediment matches closely this stratigraphic development. The freshwater lutite unit deposited in aerobic conditions shows the smallest enrichment, and the brackish-marine coccolith ooze at the bottom of the euxinic abyssal plain the highest one (Table 2; core 18). 'Dilution' of coccolith ooze by detrital clay minerals going from the central basin towards the Bulgarian coast, that is from Station 18 to 35, is reflected in a lowering of the U_3O_8 content in the coccolith ooze (Table 2). On the basis of a few analyses from core material

drilled by Glomar Challenger a similar trend seems to be established. A calcareous mud (Table 2; 379 A) deposited in aerobic conditions has little uranium, whereas the five remaining samples formed in an anaerobic environment show a 10–20-fold enrichment in U_3O_8 . The highest values again are found in the two samples from the central basin (Station 379 A).

Treatment of sample material with HCl or water, or by heat combustion, may cause uranium depletion or enrichment in the

residue (Table 2). Of special significance is the high U_3O_8 yield of the mineral ash obtained in the combustion experiment, and the release of uranium by extracting the sapropel ash with water.

U_3O_8 concentration diminishes because of: (1) loss of mineral-bound water; (2) loss of sulphur-containing volatiles, (3) loss of salts, (4) calcining of carbonates, and (5) burning of organic matter. U_3O_8 depletion is caused by: acidification, $\text{CaO-H}_2\text{O}$ interactions, and release of water-soluble uranium-organic complexes.

The bulk of the uranium seems to be bound to planktonic matter; land-derived organic debris contains comparatively little uranium. Coccoliths seem to be the prime host for uranium in modern Black Sea sediments, but other planktonic organisms share this affinity. The following tentative model is suggested to account for the enrichment.

Eukaryotic cells contain complex membraneous organelles known as the Golgi apparatus or Golgi body which occupy a central position in the transport system of the cell. For example, they fix and transport metals from within the cell to the outer membrane. This is accomplished by metal-ion coordination to specific proteins and polysaccharides which are subsequently transported to the outside. Biomineralisation is an outgrowth of this process¹¹. In the case of coccoliths, uronic acids and polysaccharide-sulphates¹² are the principal metal-ion fixers. The relationships are revealed in an electron micrograph where the organic template is stained by heavy metals, thus revealing the growth pattern of the coccolith within the Golgi body. In this way, metal ions that are not needed by the organism can be readily neutralised (Fig. 2).

Fig. 2 Heavy-metal stained coccolith, *Umbilicosphaera* sp., revealing growth pattern. Scale bar, 0.2 μm .

Uranium content of Black Sea water ranges from 1 to 7 p.p.b., (parts in 10^9) with the average ~ 3 p.p.b. (refs 13 and 14) which is about the value for standard mean ocean water. Our U_3O_8 values are within the same order of magnitude: aerobic zone (2.4 p.p.b.), interface (5.9 p.p.b.) and anaerobic zone (3.5 p.p.b.). Assuming that coccoliths fix the uranium principally during the life cycle of the organism, a 10,000-fold enrichment is observed.

Marine calcareous material of biological origin is reported to contain at most a few p.p.m. uranium¹⁵. In general, carbonates are less favourable host materials for uranium¹⁶. Thus, the enrichment of U_3O_8 in the Black Sea coccolith unit is unexpected and we are not aware of any systematic study on uranium in coccoliths. In view of the nature of the calcifying matrix in coccoliths, however, we tentatively conclude that the uronic acids and sulphated polysaccharides act as a substrate in the formation of hexavalent uranium complexes.

Non-calcareous plants may operate in the same fashion if their cell walls contain such sugars as they do in diatoms. Studies on a Holocene lake in central Ontario, for example, which is polluted by discharge from a uranium mine shows a 10,000-fold U-enrichment in the diatom-dominated living plankton over the water, that is 210 p.p.m. against 20 p.p.b. The sediments, at a water depth of 10 to 25 m, are principally diatomite and reducing in character; their U-content is between 170 and 380 p.p.m. It thus seems that reducing conditions in the depositional environment are only essential for the preservation of uranium-enriched detritus, and not for the fixation. Following sedimentation, a series of organic molecules may pick up additional increments of uranium as well as other heavy metals from sediment and water. The organic material can become stabilised by heavy-metal complexation to a point that it is finally rendered insoluble to extraction by conventional acid or base treatments.

Mass balance

The Black Sea covers an area of $4.23 \times 10^6 \text{ km}^2$, of which 30% is shelf. The basin proper, therefore, has an areal extent of $2.96 \times 10^6 \text{ km}^2$. The top 1 m sediment has a bulk density of 1.25 g cm^{-3} , which will give a sediment mass of $3.7 \times 10^{17} \text{ g}$. Combustion of total sediment at 1,000 °C will reduce weight of material by 80%; weight of remaining ash is $7.4 \times 10^{16} \text{ g}$. Average U_3O_8 content in ash (Table 2) is $90 \times 10^{-6} \text{ g per g}$ sediment. Total U_3O_8 concentration in sediment ash of top 1 m strata of Black Sea basin is $6.7 \times 10^{12} \text{ g}$ or $6.7 \times 10^6 \text{ tonnes}$.

Sapropel and coccolith ooze have been deposited over the past 5,000 yr. Assuming that uranium is extracted at a constant rate over this time, the basin sediments will annually receive $1.34 \times 10^9 \text{ g U}_3\text{O}_8$. Should this material exclusively be extracted from the aerobic water layer having a mean U_3O_8 content of $3 \times 10^{-6} \text{ g l}^{-1}$ or a total of $1.78 \times 10^{11} \text{ g U}_3\text{O}_8$ for the upper 200 m, about 1% of this amount is annually released to the sediment.

Calorimetric determination of combustion heat

Average Black Sea abyssal mud deposited over the past 5,000 yr contains per 1,000 g sample: 600 g H_2O , 100 g clay, 100 g organic matter, and 200 g $CaCO_3$. Since combustion of sediment at 1,000 °C will substantially increase the U_3O_8 content in the remaining ash, it is of considerable interest to know whether indigenous organic matter can supply sufficient energy for this reaction.

Calcining of carbonates: $CaCO_3 \rightarrow CaO + CO_2$, $E = 47.2$ kcal mol⁻¹ and evaporation of water: $H_2O(aq) \rightarrow H_2O(g)$, $E = 9.73$ kcal mol⁻¹ require a total of 418 kcal per 1,000 g of sediment. This is the minimum amount of energy needed for self-sufficient burning.

Table 3 Combustion heat values for the stratigraphic units compared with common organic compounds

Sample	Combustion heat (Kcal kg ⁻¹ at 25 °C)
Coccolith*	528
Top sapropel*	642
Bottom sapropel*	1,109
Wood†	4,500–4,800
Peat†	5,000–5,800
Lignite†	6,200–7,600
Coal†	7,600–8,750

*Samples were pre-dried at 110 °C.

†See (ref. 18).

Combustion heat was determined for three representative samples from Station 18 (Fig. 1), coccolith ooze, top sapropel, and bottom sapropel. A conventional calorimetric bomb was used and combustion heat values are given in kcal kg⁻¹ at 25 °C. Data are reported in Table 3 together with calorimetric values of common organic compounds.

Combustion heat values for the dry mud samples are considered minimum values, because part of the heat generated

during the experiment has been used for calcining, thermal degradation of clay minerals, and decomposition of sulphides. Still, these values are far in excess of the 518 kcal needed to dry and calcine a 1,000 g wet sediment.

In conclusion, heat combustion of Recent Black Sea mud will release more energy than is required for drying and thermal degradation of mineral matter. The combustion process will yield an ash with a U_3O_8 content close to 100 g tonne⁻¹. Slightly higher values are expected in those parts of the Black Sea basin which are furthest removed from river outlets and turbidite incidents. Such a region could be close to Station 379 (Fig. 1).

Although U_3O_8 values of 100 g tonne⁻¹ are not economically significant now, the situation may change in the years to come should global demand for uranium expand at predicted rates. In view of the high sulphur content of recent Black Sea mud a note of caution should be sounded, since mining of the low-grade ore may introduce environmental hazards.

The work was supported by a grant of the Deutsche Forschungsgemeinschaft. We thank Mr K.-D. Schrader for laboratory assistance.

Surface ozone concentrations at five sites in South-East England were measured during the heat wave of 1976 from 22 June to 12 July. At all sites peak hourly concentrations were the highest ever recorded in the UK and the elevated levels persisted for periods longer than any previously measured. Some discussion of the significance of the results is given together with an analysis of back-track air mass trajectories in the context of oxidant formation in North-West Europe.

We have previously reported measurements of atmospheric ozone in urban and rural areas of southern England during the period 1971–75 (refs 1–5). Although, on occasion, the levels exceeded the US (US EPA) air quality standard of 80 p.p.b. (volume parts per 10⁹, ~ 160 µg m⁻³) maximum 1-h mean⁶, the World Health Organisation (WHO) long-term goal of 60 p.p.b. 120 µg m⁻³ (ref. 7) and the Greater London Council (GLC) guideline of 80 p.p.b. (160 µg m⁻³) (ref. 8), the occurrence of elevated levels was, in most instances, confined to irregularly spaced episodes of only a few days duration. During 1976, the unusual meteorological conditions prevailing between 22 June and 12 July

Fig. 1 Ozone and temperature levels during the photochemical episode. \circ --- \circ , temperature at noon, mean of readings at Kew, Gatwick and Heathrow ($^{\circ}\text{C}$). \circ — \circ , highest hourly mean ozone concentration for each day at Stevenage, p.p.b. (parts in 10^9).

resulted in a period particularly favourable for photochemical production of ozone. We present here data showing that the ozone concentrations at all our measuring sites were both higher and more persistent than any we have monitored previously. To illustrate the broad features of the persistence of elevated levels in South-East England during this period we have plotted, in Fig. 1, the highest hourly mean ozone concentration for each day at one of our sites (Stevenage) against the temperature at noon (mean of readings at Kew, Gatwick and Heathrow).

Ozone concentrations are reported from five locations in South-East England, three within the Greater London conurbation and two outside in rural (Harwell) and semi-rural (Stevenage) environments. The Greater London sites were carefully chosen to minimise the effect of local sources of nitric oxide (NO) which is initially a rapid scavenger of ozone. In the centre of London, where this is difficult to achieve, a rooftop site overlooking a courtyard was chosen (Islington, on the City boundary). The suburban sites (Hainault and Teddington) were in mixed open parkland/residential locations. The Warren Spring Laboratory site lies on the western edge of Stevenage New Town with open country to the south and west. Two local sources of NO are a light industrial area to the north and the A1(M) motorway some 40 m to the west. The only significant sources of NO at the Harwell site are likely to be traffic on the A34 road ~1.5 km to the east and vehicles on the AERE site itself. The locations of the sites are shown in Fig. 2, and specific site details in Table 1.

Three sites were equipped with ethene-chemiluminescence⁹ (EC) ozone monitors and two with instruments operating on the ultraviolet absorption principle¹⁰ (UV).

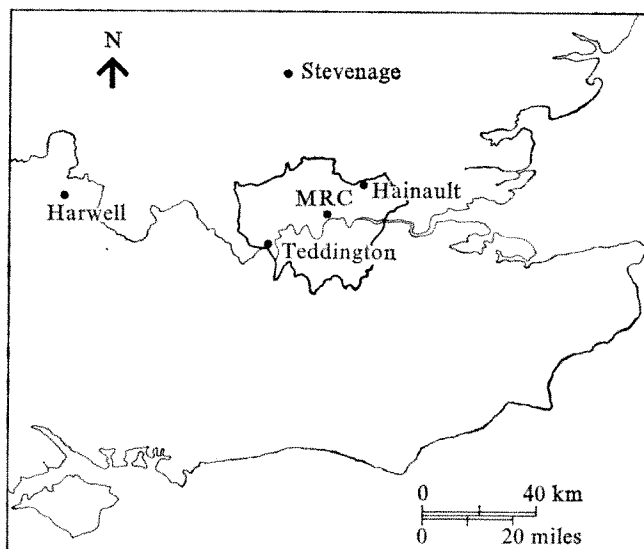

Fig. 2 Sketch map of South-East England showing location of sampling sites.

We have attempted to quantify the similarities and differences between the sites by investigating the correlations between the hourly mean ozone concentrations for each pairing of sites and the results are shown in Table 2. Initially, hourly values from one site were regressed against the concentrations for the same hours at each of the other sites in turn. The results in Table 2 show, that, in general, the Harwell ozone levels are higher than the other sites for which no general pattern can be distinguished. We then investigated, for pairs of sites, the correlations of hourly values displaced relative to one another, that is hour n for site A was correlated with hour $n+m$ of site B. This was done for all pairs of sites for values of m from -11 to +11. It was found that for all pairs of sites not involving Harwell,

Table 1 Site details

Site	Site description	Height above ground (m)	Instrument	Calibration
City (C)	Courtyard in centre of Greater London ~70 m from nearest street	20	EC	KI
Hainault (Ha)	Suburban London. Open country to S and E, otherwise residential	4	UV	KI + gas phase titration
Harwell (H)	Rural, 1.5 km from A34 trunk road	2	EC	KI + optical extinction
Stevenage (S)	Light industry to N, motorway 40 m to W, residential to E, otherwise open country	10	EC	KI
Teddington (T)	Suburban London. Open parkland to S, residential to N	13	UV	KI + gas phase titration

Table 2 Inter-site correlations of ozone levels for 1976 episode

Site versus Site		Lag* (h)	Correlation coefficient	Mean regression†	Significance level of correlation coefficient change with lag (%)
H	S	0	0.78	$S = 0.77H - 7.9$	
H	C	0	0.74	$C = 0.72H - 13.2$	
H	T	0	0.74	$T = 0.72H - 7.7$	
H	Ha	0	0.67	$Ha = 0.73H - 11.3$	
H+1	S	1	0.80	$S = 0.77H - 7.8$	79
H+1	C	1	0.76	$C = 0.71H - 12.7$	77
H+1	T	1	0.81	$T = 0.72H - 7.4$	99
H+2	T	2	0.81	$T = 0.72H - 7.5$	99
H+1	Ha	1	0.72	$Ha = 0.73H - 10.5$	91
H+2	Ha	2	0.73	$Ha = 0.73H - 10.4$	93
S	C	0	0.78	$C = 0.93S - 5.5$	
S	T	0	0.86	$T = 0.94S - 1.5$	
S	Ha	0	0.81	$Ha = 0.94S - 2.8$	
C	T	0	0.81	$T = 1.0C + 5.5$	
C	Ha	0	0.88	$Ha = 1.0C + 2.7$	
T	Ha	0	0.81	$Ha = 1.0T - 2.8$	

H, Harwell; S, Stevenage; C, City; T, Teddington; Ha, Hainault.

*For example, H+1 means hour $n+1$ for Harwell was correlated with hour n for other sites.

†Mean of y on x and x on y .

the correlation coefficient for $m=0$ was highest. In contrast, for correlations of Harwell values against those from all other sites, improved correlation coefficients were obtained with $m = +1$ or $+2$, that is, better correlations were obtained by regressing hourly values from the other sites against later hourly values at Harwell. Two points emerge clearly from this analysis; the results for the Stevenage site are similar in magnitude and diurnal pattern to the Greater London sites and Harwell is significantly different from each of the other sites in both respects. The explanation of both points is in part linked with local emissions of NO and the close proximity of the light industrial area and motorway turning the otherwise rural aspect of the Steven-

age site into a more urban situation while the relatively low NO levels at Harwell lead to less ozone depletion. The important conclusion is that, in common with the Los Angeles area¹⁹ it is the rural areas downwind of the primary pollutant sources which experience the higher ozone levels.

The maximum 1-h mean concentrations of ozone measured at each of the sites exceeded those previously reported by considerable margins (see Table 3).

During the 21-d period 22 June to 12 July the numbers of hours above 100 p.p.b. within Greater London were 85, 86 and 100 at the City, Hainault and Teddington sites and 115 and 158 at Stevenage and Harwell, outside Greater London. The total number of hours above 100 p.p.b.

accumulated during the whole period 1971–75 at the Harwell site was exceeded in this one 1976 episode. For the first time in the UK, urban levels exceeding 200 p.p.b. and rural levels exceeding 250 p.p.b. were measured. At each site there was a continuous period of 5 d or more (Table 4) when the ozone concentration exceeded 100 p.p.b. for at least 8 h each day. Thus the industrial threshold limit value (TLV)¹⁵ was exceeded at all our sites in the outside air in South-East England for the equivalent of a working week. In this analysis the duration of high concentrations at Stevenage was intermediate between that in the urban and rural extremes of London and Harwell. Although these levels were high in comparison with the air quality guides and industrial threshold limit values cited above, it is not possible to evaluate their direct significance in terms of human health. Comparison with the TLV is not necessarily appropriate for such limiting values are intended for use in evaluating health risks for the occupationally exposed. For the general population, which includes the young and the infirm, a further margin of safety is usually regarded as prudent.

The US air quality standard and the WHO long term objective are more stringent than the TLV. Both were exceeded during 1976; but, they are also exceeded in the US and in many other developed nations. There was a sharp increase in mortality in Greater London at the time of this episode¹⁸ but effects due to anything other than the high prevailing temperatures could not be isolated. During early July serious damage was observed on two crops of tobacco plant (Bel-W3) grown specifically to test for oxidant effects at Leeds and at the Fairfield Experimental Horticulture Station, Kirkham, Lancashire (J. T. Fletcher, personal communication). High percentage leaf damage would be anticipated on the basis of models of tobacco plant injury¹⁶ and the ozone concentration reported here. No effects of elevated oxidant levels to any other types of plant were reported during the episode.

Elevated ozone levels in the UK have generally been associated with anticyclones to the east of the UK³ and to this extent the photochemical episode of 22 June to 12 July was typical. In such cases the air mass trajectories over

southern England are easterly and in general cross NW Europe. Typical back-track trajectories are illustrated in Fig. 4. Those for 27 June and 3 July describe the history of the air mass reaching South-East England on two of the days of particularly high ozone concentrations. On 7 July the levels at most sites had begun to decrease and 9 July, the trajectory for which shows a south-westerly air flow over South-East England, was the day on which all sites showed their lowest daily maximum hourly mean ozone concentration throughout the episode.

A closer study of individual back-track trajectories highlights a number of factors which must be borne in mind

**Fig. 4** Back-track air mass trajectories for four selected days during the photochemical episode. The location of the air mass at various times in hours before its arrival at midday in London is indicated on each trajectory. *a*, 27 June; *b*, 3 July; *c*, 7 July; *d*, 9 July 1976.

if an abatement policy for photochemical oxidants were to be considered. First, generation of ozone requires several hours of solar irradiation of the primary pollutant plume even with the more reactive hydrocarbon precursors so that photochemical ozone is usually first detected 50 km or more downwind of the primary source¹⁷. In the densely populated and highly industrialised regions of North-West Europe this makes source identification difficult. Second, photochemical ozone can be transported over hundreds of km from source regions in North-West Europe with the limited deposition at sea surfaces and because ground-based nighttime inversions typical of anticyclonic weather isolate the ozone formed during the day from ground sink surfaces over rural areas³. Third, primary NO emissions, while constituting an important precursor of photochemical ozone are initially a potent sink for ozone in more polluted areas and the emission and dispersion pattern of NO will have a major effect on ozone concentrations measured close to the ground. These factors tend to obscure any simple interpretation of the effect of a particular precursor source region.

As an example, we consider here the trajectory of 3 July (*b*, in Fig. 4). The air mass present over South-East England on 3 July had travelled across southern Poland, a possible

Table 4 Maximum number of consecutive days with ozone > 100 p.p.b. for at least 8 h

Location	No. of days	Longest period
City	5	24 June–28 June
Hainault	5	24 June–28 June
Teddington	6	3 July–8 July
Stevenage	10	1 July–9 July
Harwell	18	22 June–9 July

area of precursor emission, about 45 h previously. Then there was about $\frac{1}{2}$ cloud cover reducing the radiation flux and a temperature of about 25 °C so that photochemical activity was probably limited. Throughout the afternoon of 2 July the air mass traversed central West Germany with clear sky conditions and temperatures of 30 °C. The conditions for precursor injection and photochemical transformation were potentially excellent. By the morning of 3 July the air had reached the industrial areas and refineries of the Thames estuary, also potential sources of precursors, with clear sky conditions still prevailing. At this time the air mass was moving at about 400 km d⁻¹, although surface winds were only 4–10 km h⁻¹. Thus several hours later the air reached central London where maximum ozone values were recorded during the period 1400–1600 BST. The air mass which gave rise to the elevated ozone levels on 3 July, therefore, had 3 d with probable precursor injection and two full days of exposure to strong sunlight and high temperatures during which the ozone was formed. The history of air over London on other days in this episode with high recorded ozone levels was similar.

It has previously been noted that the data for Greater London follow a pattern which is consistent with the mechanism of local generation of ozone, both from the point of view of precursor emissions and the concentration gradient of ozone across London from east to west^{2,4}. That proportion of the total ground level ozone concentration which is produced locally is difficult to estimate solely from ground-level measurements. The complexities of the air mass trajectories presented here and the likely emissions of precursors along their paths together with considerations of precursor reaction times and NO emissions all tend to merge local production into the general pattern of secondary pollutant formation in North-West Europe as a whole.

Our further understanding of this phenomenon and the

role of various primary pollutants clearly requires the co-operation of other European countries, upwind and downwind of the UK, in ozone and precursor measurement programmes. Data on the occurrence of high ozone concentrations in North-West Europe in the period 1971–75 have been assembled in a recent publication²⁰ and we would welcome the further publication and/or exchange of relevant data from those areas which the back-track trajectories indicate to be of importance in oxidant production.

We thank Dr F. B. Smith (Meteorological Office, UK) for help in calculating the trajectories. The measurements carried out at AERE and at Warren Spring Laboratory were part of a programme sponsored by the Department of the Environment.

Palaeoclimates of Central Sahara during the early Holocene

J. Maley

Laboratoire de Palynologie, USTL, 34060 Montpellier, France.

In the Central Sahara lying approximately between 27°N and 18°N, rains were primarily due to tropical depressions in the early Holocene up to about 6500 BP. Then the monsoon rains of Sahelian type dominated up to about 4400 BP.

POLLEN analysis was carried out on Holocene lacustrine deposits¹ sampled every 10–20 or 30 cm in a section of about 7.80 m at Tjéri (13°44'N–16°30'E) near the centre of the great Palaeochad^{2,3} (Fig. 1). Chronology of the Tjéri section was established by two radiocarbon dates on organic material near the base (Fig. 2) and, for some other levels, by correlations with notable events radiocarbon dated elsewhere in the zone of the Palaeochad^{1–3}. The chronology established in the Nile valley (see below) and elsewhere in the southern part of the Sahara gives some valuable correlations¹. Approximate dating of the intermediate levels was established by rates of sedimentation. About 60 yr elapsed for each 10 cm from 9000 to around 7000 BP and about 220 yr from then till about 4000 BP. The change in rates of sedimentation at about 7000 BP could parallel the important change in conditions noted for the Blue Nile at about 7000 BP (ref. 4).

In the dry tropical zone where the Chad basin is situated, the rainfall and its distribution through the year are the most important climatic factors controlling the vegetation and its spatial distribution. Thus there is a direct relationship between vegetation and climatic pattern. In the Chad basin the regular succession of climatic and vegetation zones is a favourable factor for pollen analysis⁵. On the Tjéri section 46 samples were studied and for each about 1,000 to 6,000 pollen grains were counted. The Gramineae, Cyperaceae and *Typha* pollen grains represent about 80 to 90% of each total. Therefore those 3 taxa have been eliminated from the pollen sum and studied apart in order not to distort the percentages of all other pollen grains more typical. Those pollen grains were classified according to the present geographic distribution of the taxa to which they belong and the most typical were placed in four phytogeographical elements covering the four major vegetation zones of the Chad basin, that is, (from S to N) Sudano-guinean element (plants typically growing under 1,500 to 1,000 mm rain per annum), Sudanian element (1,000 to 500 mm), Sahelian element (500 to 100 mm), Montane (Tibesti) element (plants growing at the nearest on the upper Tibesti Plateaux) and also in a group of hygrophilous plants⁵. The relative percentages of the pollen grains for these four elements were used to construct curves which portray the climatic variations occurring in the four zones of the Chad basin¹.

Palaeoclimatic pattern of the Sahelian zone

Comparison of the Sudano-Guinean element and Sahelian element curves showed that the periods of climatic optima (relatively wetter phases) are in general out of phase with each other¹ (Fig. 2). It seems also that during the Holocene, the Sahelian climatic optima have always been synchronous with the warming periods, and the deteriorations with the coolings. Indeed the trends of the Sahelian curve at Tjéri—the amplitudes of variations being different—correlate well with the trends which appear on some curves portraying the evolution of the temperature on the Northern Hemisphere, such as that of Camp Century in Greenland^{6,7}. For the most part of the Holocene, it seems that the Camp Century curve is quite well dated: first, the counting of annual layers was possible with some correction until 8300 BP (ref. 7); second, for the Holocene this curve has good cross-checkings with various eustatic curves⁸⁻¹⁰, with the fluctuations in the

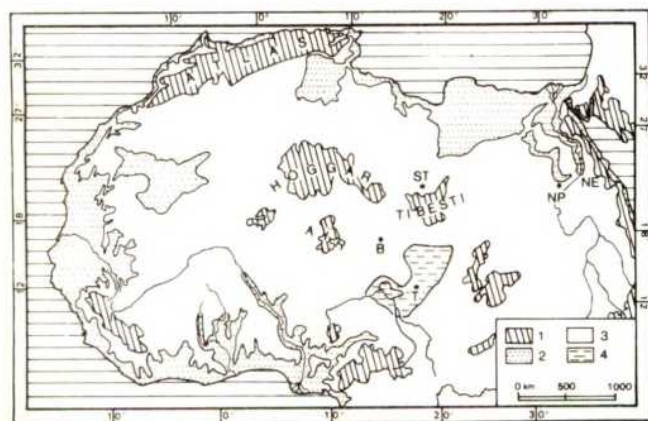

Fig. 1 North Africa. 1, Mountains over 1,000 m. 2, Regions under 200 m. 3, Regions between 1,000 m and 200 m. 4, Holocene Palaeochad, 320 m high. T, Tjéri. B, Bilma. ST, Sérir Tibesti. NP, Nabta Playa. NE, Egyptian Nubia.

atmospheric radiocarbon level^{11,12}, with glacier fluctuations in the Alps¹³, and so on. Comparison of the Sahelian curve with that of Camp Century shows that the lowering periods of the Sahelian curve, which correspond to aridification periods in the Sahel zone, correspond also to cooling periods, and vice versa¹. Study of diatoms^{2,14} and pollen in the same samples provides a direct and important corroboration of this phenomenon. Indeed, from about 8000 up to about 4000 BP, the high percentages of a psychrophile ('cold') diatom *Cymatopleura elliptica* or of a diatom of temperate type *Cyclotella ocellata* occur during the phases of relative lowering or minima of the Sahelian element (Fig. 2). Considering these different correlations, one can also use the curve of Camp Century as a basis for an explanation of the Montane element.

The Montane (Tibesti) element

Pollen spectra of Tjéri also showed small percentages (average 3.1%) of very characteristic taxa originating from more northern regions (*Artemisia* sp., *Pentzia monodiana*, *Erica arborea*, *Ephedra* sp., *Plantago* sp., *Silene* sp.). When many pollen grains are counted on successive samples of the same section, the variation of very low percentages can be used with some confidence—as, for instance, in a pollen study of the west part of the Sahara¹⁵. The pollen grains assigned to the Montane element must surely have been brought to Tjéri by the prevailing wind, that is, the harmattan, blowing from about NE or N. The water transport of pollen grains across the whole actual lake Chad is very limited⁵ and probably was so for the Palaeochad, particularly for pollen grains coming from the Tibesti, because the nearest fluvial source was about 450 km from the station studied. For these pollen grains, the nearest sources at present are some 700 km to the north on the High Plateaux of the Tibesti¹⁶. Further north, other important sources of *Artemisia*,

for instance, are found only on the narrow Mediterranean zone of Libya, about 2,000 km from Tjéri. But the latter sources seem unlikely to be involved, because other pollen types present in the Mediterranean zone of Libya, such as Cupressaceae or *Quercus*—very easily carried in the atmosphere¹⁷—would have been found at Tjéri. In conclusion, the pollen grains of the Montane element originate most probably from the Tibesti.

Comparison of the early Holocene pollen curves for the Sahelian and Montane elements shows (Fig. 3) a rough synchronicity in terms of thousands of years and a good synchronicity for the main aridity maxima. This second point shows that the percentage variability of the Montane element is not governed by variations in intensity of the harmattan, as the aridity maxima coincide with maxima of eolian activity. On the other hand, thanks to the chronology established at Tjéri, it seems that the different pollen maxima of the Montane element show good correlations with the different geological and palaeoecological events radiocarbon dated in the Tibesti (Fig. 2, Table 1). These correlations also increase the reliability of the pollen curve.

The Middle Terrace

In the Tibesti, the early Holocene coincides with the end of the accumulation of the so-called 'Middle Terrace' (MT)¹⁸⁻²³ (Fig. 2). A radiocarbon dating in the lower part of the MT gave a date of 14055 ± 135 BP (ref. 20). It is possible that the base of the MT in the Tibesti began about 17500 BP like the

Fig. 2 Comparative evolution for the Tjéri station, from base to top. a, Relative lacustrine levels, after diatom studies^{2,14}. The ? at 4,20 m is the author's interpretation¹ and a brief regression at 3.80 m (around 6600 BP) is also probable. Some diatoms of ecological importance: SA, *Stephanodiscus astrea* var. *minutula*; F, *Cymatopleura elliptica*; T, *Cyclotella ocellata* (relative scale). b, Dotted lines, pollen curve for the Sudano-Guinean element (relative %, mean: 20.2%). β , Present time % (two samples). c, Solid line, pollen curve for the Sahelian element (relative %, mean: 33.9%). α , Present time % (two samples). These two curves (b, c) were constructed using the ratio with the mean (value of 1) carried out on the whole of the levels studied (log scales). On this scale, the value of zero was arbitrarily fixed at -100. d, Chronology reconstituted after various regional correlations. Near the base, two radiocarbon dates: at 7.75 m, 9000 ± 200 BP; at 7 m, 8750 ± 200 BP. The dates are given in BP except for the last two millennia in AD (calendar years from ref. 12). e, Schematic curve of the $^{18}\text{O}/^{16}\text{O}$ ratio for the ice core at Camp Century (Greenland) adapted from M. Ters (ref. 10); from 9000 to 1700 BP after ref. 7 and from 1700 BP to the present after ref. 6. Figure reproduced from ref. 1 with kind permission.

base of the equivalent formation in Nubia (Malki Member of Ineiba Formation)^{24,25}. In general, throughout all the Tibesti, the stratigraphic and sedimentological evolution of the MT, especially the upper part, is constant¹⁸. Some sections with radiocarbon dates facilitate the precise dating of the occurrence of the principal events intervening during the accumulation of the upper part of the MT. For the phases A, B, C, in some craters or depressions throughout the massif, there are lacustrine deposits chronologically equivalent^{18,19,26}. The accumulation of the MT occurred in several phases separated by calcareous crusts, the most recent of which were principally formed about 9200–9300 and 7600–7300 BP (D phase)^{20–22}. By correlation with the Montane element curve, it seems that the last calcareous crust formation corresponds to an arid period (see below). At the end of the D phase, a small erosion occurred before sedimentation started again. This discontinuity is a very characteristic feature. The last phase of bedded deposits (E), sometimes with coarse material, exhibits in some places, before the beginning of phase F, a thin brown palaeosol rich in organic matter^{23,28}, which was dated 6600±140 BP at Mouskorbé (Gif n°3228). In Nubia, a palaeosol with kaolinite (Omda soil) was described and situated approximately at 7000 BP (ref. 24).

At the top of the MT, phase F represents a very clear sedimentological change, that is, a dramatic increasing amount of pebbles and cobbles. This phenomenon, which had started after 6600 BP, is general across the Tibesti and the Central Sahara at the top of formations equivalent to the MT. This sudden influx of pebbles is surely related to a change in climatic regime. Then the erosion of the MT (phase G) to below the actual level of the rivers could occur between about 5500 and 4000 BP. In the Tibesti, during the following H phase approximately dated 4000–2000 BP, a Lower Gravel Terrace was deposited^{18,19}.

The upper part of the MT with its main characteristics or some equivalent lacustrine deposits, can be found in many regions of the Central Sahara—for the MT, in the Hoggar^{18,27}, in Central Aïr³ and in Egyptian Nubia (Sinqari Member, upper part of Ineiba Formation and Shaturma Formation, Member I)²⁴ (Table 1). For the lacustrine deposits, the depression of Nabta Playa²⁸ (altitude about 300 m) about 100 km west of Abu Simbel, exhibits a stratigraphic succession and lacustrine phases with prehistoric occupation sites closely correlated with the events of the Tibesti (Table 1). The Terminal Palaeolithic II (or Epipalaeolithic), though without radiocarbon date, corresponds most probably to the climatic optimum B of the Tibesti (about 8400–8250 BP). On the other hand, near Bilma in the Ténéré (18°40'N–13°E; altitude about 360 m) the early Holocene lacustrine deposits³ can be correlated with phases A, B, C of the Tibesti (Fig. 3). In Adrar Bous (20°18'N–9°E; altitude about 700 m) early Holocene lacustrine deposits are radio-

carbon dated before 7310±120 BP (refs 29, 30). In the middle of Serir Tibesti (23°30'N–17°20'E; altitude about 500 m) lacustrine deposits about 10 m thick are dated of the early Holocene³¹. Thus all these correlations suggest that during the early Holocene the climatic conditions were similar and apparently synchronous throughout all the Central Sahara. Therefore, the local factors seem to have had but a limited action.

One typical section of the MT for the early Holocene was chosen in order to show the correlations with the evolution of the Montane element of Tjéri (Fig. 3). This section was taken by J. Grunert²³ near Yebbi-Bou (20°53'N–18°4'E; altitude about 1,440 m) on the north side of the Tibesti. A radiocarbon-dating on shells at about 2.5 m (8180±70 BP) locates this section in the chronological framework of the Tibesti and the Central Sahara.

Palaeoclimatic interpretation

To try to understand the palaeoclimates of the Tibesti in the early Holocene we can compare the pollen curves for the Montane and Sahelian elements (Fig. 3c, d). The system of representation (the ratio with the mean) facilitates direct comparison for the two curves (see other examples in refs 5, 17). Thus, from one sample to the next we can see completely opposite trends, or similar trends but of very different amplitude. Although in the scale of thousands of years there is a rough synchronicity between the curves for these two elements, the opposite trends shown up by detailed analysis imply that the rains were of different origins in the Sahel zone and the Tibesti.

For palaeoclimatological interpretations it is necessary to use as climatic models meteorological situations and climatic patterns of the present time. For instance, in Aegean regions, the climatic pattern of one winter was used to explain that of the period around 1200 BC (ref. 32); or seasonal change through the year was used to explain some aspects of the past climatic changes³³. Here the present evolution of the Saharian climate through the year is used in an attempt to establish the climatic pattern of this region in the early Holocene.

Climatic model for the present time

At present nearly all the rains falling in the Sahel zone are monsoonal in origin. In summer (July–August) these rains reach the Hoggar and Tibesti mountains^{34–36}. But, over the Central Sahara the heaviest rains fall chiefly during the intermediate seasons of spring (March–June) and autumn (September–December)^{35,37,38}. The study of the cloud formations over the Sahara also confirms the importance of the intermediate seasons³⁹. The rains of inter-

Table 1 Early Holocene events and correlations between Tibesti, Nabta Playa and Egyptian Nubia

	(?) 9300–9000	Aridity		

Note that in other places the Neolithic begins in 8065±100 (Tibesti), 8072±100 (Acacus), 8100±130 (Tassili), 8100±130 BP (Hoggar)³⁸.

seasons are linked with the tropical depressions^{34,40-43} also called Sudano-Saharan depressions³⁵ or 'Khamisin' depressions in Eastern Sahara^{44,45}. Rains of this type are often fine and continuous⁴⁶, whereas the monsoon rains are stormy. At present these depressions occur rarely in winter except in Western Sahara (Senegal, Mauritania: 'Heug' rains^{34,35}). On the other hand, these depressions are absent in the height of summer when the ITCZ reaches the Sahara. Schematically the synoptic situations are as follows⁴¹⁻⁴⁶: (1) influx of polar air in the middle or upper troposphere above the Sahara along shallow troughs in the upper westerlies and (2), frequently, ahead of these cold troughs, undulations occur in the ITCZ with brief invasions of humid equatorial air. The undulations of the ITCZ could be due to the action of boreal cold troughs or to surges of monsoon caused by perturbations travelling in the Southern Hemisphere⁴⁶. The depressions created by the cold air aloft favour the advection of the equatorial humid air. In this part of the year the movements of these depressions are north-eastwards or eastwards³⁵. The advection of humid equatorial

an example, two Gramineae, with close taxonomic affinities, *Aristida meccana* and *A. mutabilis*, have geographic distributions which exhibit the same pattern. The first one has an area restricted to the Central Sahara, the second a Sahelian area with some stations in the Central Sahara in zones exposed to the monsoon⁴⁹. I consider that this opposition Sahel-Central Sahara, can only be explained by the hypothesis of different origins for the rains, that is, the direct monsoon and the tropical depressions. Thus this opposition must no doubt be comparable with that which existed over longer periods in the early Holocene.

Application of the present model in the early Holocene

The dominance of tropical depressions over the Tibesti seems to be proved, especially between around 8000 and 6500 BP, by the fact that the fluctuations of the curve for the Montane element approximately follow those of the present tropical depressions over the Sahara through the period of 1 yr (refs

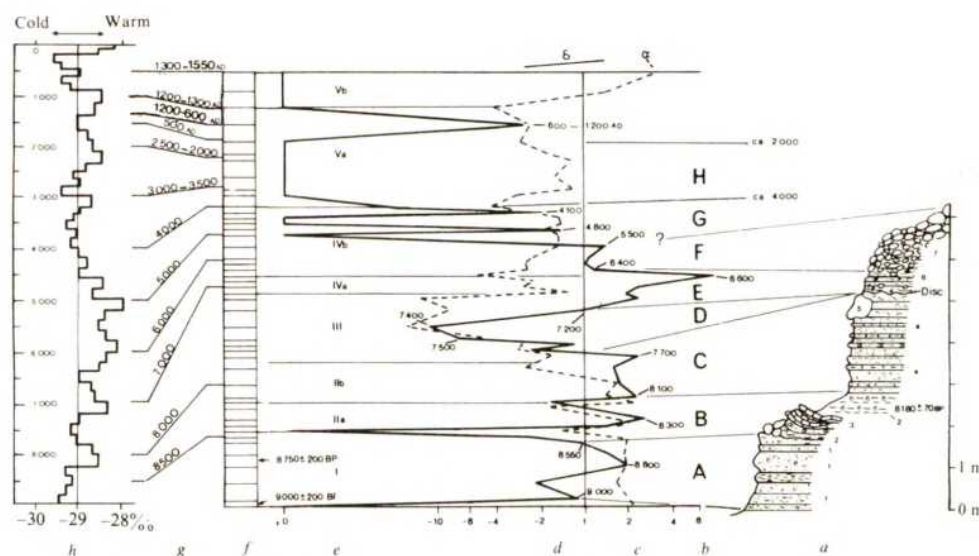

Fig. 3 Comparative evolution of the MT in the Tibesti, of the pollen curves for the Montane and Sahelian elements and of the $^{18}\text{O}/^{16}\text{O}$ ratio at Camp Century. *a*, 'Middle Terrace' (MT), section near Yebbi-Bou, after J. Grunert (23, pr. 20). 1, Indurated layers with coarse sands, bedded towards the base and becoming silty towards the top. 2, Compact silts with shells. air is essential for the formation of rain from these depressions. At present in winter, the scarcity of these depressions over the Sahara, except the western part with 'Heug' rains, can be explained by the fact that at this time of the year the ITCZ is situated at very low latitudes. But when there is interaction between cold troughs and the ITCZ, the trajectory of depressions remains chiefly over the Sudan and Sahel zones³⁴⁻³⁶.

A study of all rainfall data available since the beginning of the century for Africa north of the equator was carried out⁴⁷. It showed, by the method of spatial correlation of annual rainfalls, that in some years there is a clear opposition between the Sahel and Central Saharian zones. Either the Central Sahara gets heavy rains and the Sahel low or average rainfall, or vice versa. The phenomenon is less clear for Eastern Sahara, due to the lack of sufficient data and to the probability that the trend for the whole Central Sahara is only apparent for longer periods. Thus, for instance, only anomalies over 30 yr have a similar trend through the Mediterranean area⁴⁸. Nevertheless, this climatic opposition is genuine because it had an effect on the distribution, and perhaps the evolution, of some taxa. To give

37, 38, 45), when in the Northern Hemisphere temperatures are rising (spring) or falling (autumn). When temperatures are at their lowest (winter) these depressions are infrequent and when at their highest (summer) they do not occur. Between 8000 and 6600 BP the following correlations appear between the trends of temperatures on the Northern Hemisphere ($^{18}\text{O}/^{16}\text{O}$ curve at Camp Century^{6,7}, see above) and those of the curve for the Montane element (Fig. 3 *h*, *c*).

At around 8000–7700 BP—temperature is falling (autumn climatic model)—the Montane curve is at a maximum. At 7500–7400 BP—temperature and Montane curve are at a minimum (winter climatic model). At 7400–7100 BP—temperature is rising (spring climatic model)—there is a strong positive trend in the Montane curve. At 7100–7000 BP—temperature reaches a maximum (summer climatic model)—there is a slight drop in the Montane curve. At the same time a brief optimum occurs for the Sahelian element¹. At 7000–6600 BP—temperature is falling (autumn climatic model)—there is a strong positive trend in the Montane element curve.

Possibly this type of correlation existed before 8000 BP, but

the data available are not sufficient to allow us to demonstrate it. A consequence of this climatic pattern is that the climatic optima in the Tibesti lasted longer than those in the Sahelian zone, as is clearly evident between 8000 and 7000 BP (Fig. 3c,d). For the optima of the Tibesti, the climate consisted probably of rains fairly well distributed throughout the year, with two principal rainy seasons, one in spring, the other in autumn and with a strong reduction of the evaporation (see the lacustrine deposits). It should also be noted that the disappearance of the 'cold' diatom *Cymatopleura elliptica* in the Palaeochad (2, 14), dated after about 6600 BP at Tjéri (fig. 2) occurs just before the appearance of a warmer climate of Sahelian type (see below). Moreover during some years or periods with large seasonal contrasts (very cold winters and very hot summers), there could have been a combination of rains from tropical depressions and from the monsoon, as can sometimes be observed in present years^{37,42}. This could account for the alternation of finer and coarser layers in phase C of the MT. Finally for the climate of the Tibesti during the arid phases, of which phase D is a good example, we could perhaps imagine tropical depressions in winter and, possibly, with snow³⁵, the rest of the year being almost without rain, which would cause intense evaporation favouring the formation of calcareous crusts. Cyclonic rains from the Polar front in surface are also possible in winter without the intervention of equatorial air. But since the cold air carries little humidity, these rains would in general be relatively light^{34,50}.

Interpretation of the upper part of the MT

From around 6500 to 5500 BP, the relationship with temperature seems to be different (phase F). The trends of the curves for the Montane and Sahelian elements become similar. One may thus suppose that during this time the Tibesti underwent the same regime as the Sahelian zone, which means that almost all rains would be provided by the summer monsoon.

First, the sudden massive appearance of the pebbles and cobbles near the top of the MT is subsequent to 6600 BP, as the palaeosol radiocarbon dated about 6600 BP is itself covered by 40 cm of coarse alluvium²⁸. On the other hand, the spreading of the pebbles requires a very heavy fluvial regime for which rains of Sahelian type can easily be accountable. However one must note that this spreading occurred over the MT without apparent erosion. The erosion period of the MT is not yet well placed in time: perhaps after 5500 BP and before 4000 BP (Fig. 3). In Central Air, the presence of vertisols with calcareous nodules of dates 5680 ± 110 and 5010 ± 110 BP (ref. 3) indicate a wetter climate of Sahelian type. In Adrar Bous a vertisol has been situated between 7300 and 4500 BP (ref. 30). In Egyptian Nubia Member I of the Shaturma Formation²⁴ has a chronology and sedimentology corresponding to the phase F of the Tibesti. The alluviation of Member I ceased before the initiation of a renewed period of Nile dissection which occurred after 5000 BP (ref. 24). The end of Member I and the beginning of the erosion can thus be dated between around 5500 and 5000 BP. Butzer and Hansen²⁴ conclude that these deposits "imply rather effective sheet-flooding with 50 to 100 mm of rainfall at most".

A climate of Sahelian type over the Tibesti and probably also over the Central Sahara is all the more probable as other pollen data at Tjéri indicate a northwards movement of the Sahel zone at that time. The removal of the Sahelian vegetation northwards would explain the flat of the curve for the Sahelian element between around 5500 and 4400 BP (Fig. 2c). This interpretation is corroborated by the curve for the Sudanian element which reached its maximum between around 5900 and 4400 BP (ref. 1), corresponding no doubt also to a slight northwards movement of the Sudanian zone.

Conclusion

First, it seems that for the Central Sahara there are two kinds of wetter periods (optima)—one, more frequent in the Quaternary period, with tropical depressions and temperature relatively

low, and the other with direct monsoon rains and higher temperatures. Second, the annual climatic mechanisms of the present time enable the palaeoclimates of the early Holocene to be coherently explained. The opposition, both seasonal in the present time, and for longer periods during the early Holocene, between the tropical depressions and the monsoon rains can be interpreted by variations in trends of temperature over the Northern Hemisphere and also by variations in general atmospheric circulation. Indeed, the penetrations of the polar troughs aloft, necessary for the formation of tropical depressions, are related to the occurrence of large amplitude waves in the upper westerlies. On the other hand, during hotter years or periods, the polar troughs towards lower latitudes are much less frequent and the circulation of the upper westerlies becomes more zonal. This situation leads to a diminution of tropical depressions, favouring, in contrast, the extension of monsoon rains over the Sahara^{51,52}. But the opposition between these two kinds of rain remains only partial since both are also linked to the activity of the ITCZ. Better knowledge of present events as well as the study of other old periods should allow greater precision in this field.

I thank M. Van Campo, H. H. Lamb, J. Dubief, K. W. Butzer, B. Messerli and P. Guinet for comments, F. Wendorf who provided unpublished data and M. Servant the Tjéri samples, G. Delibrias (Gif) for radiocarbon dating, G. Vignard, M. Skeffington for technical assistance. This work was completed at the Palynological Laboratory of CNRS(ER.25) in Montpellier. Financial and technical support was provided by the Office de la Recherche Scientifique et Technique Outre-Mer (ORSTOM), Paris.

Dispersal in stable habitats

W. D. Hamilton

Imperial College Field Station, Silwood Park, Ascot, Berkshire, UK

Robert M. May

Department of Biology, Princeton University, Princeton, New Jersey 08540

Simple mathematical models show that adaptations for achieving dispersal retain great importance even in uniform and predictable environments. A parent organism is expected to try to enter a high fraction of its propagules into competition for sites away from its own immediate locality even when mortality to such dispersing propagules is extremely high. The models incidentally provide a case where the evolutionarily stable dispersal strategy for individuals is suboptimal for the population as a whole.

In nature, adaptations for dispersal are ubiquitous and are often applied in almost suicidal ventures or in ventures which seem too feeble to be worthwhile (such as dehiscent seeds that fall only a few feet from the parent plant). This behaviour is clearly advantageous if the habitat is unstable or offers many empty, if transient, patches. We discuss here some simple models that help to explain why such dispersal is also advantageous even in stable and saturated habitats.

To begin, we consider a wholly parthenogenetic species in an environment that provides a fixed number of sites, at each of which just one adult can live. In a fixed season at the end of its life each adult produces a certain constant number of offspring, m . A fraction ν of these are programmed to be migrants (for example, insects provided with wings and appropriate instincts, seeds with a pappus for wind dispersal). The remaining fraction $(1-\nu)$ are destined to be sedentary competitors for the home site. The mother's genotype, by means of some maternal influence on each ovum (or testa or fruit), determines the fraction ν . When ready, at about the time of the mother's death, the migrant offspring take off and after mixing with all other migrants, and suffering a mortality such that only a fraction p survive, they are distributed equally to all the sites. There they compete on equal terms with the resident young which, it is supposed, up to this stage suffer no mortality (alternatively, if they do, p is the relative survival of the migrants). In effect, one offspring is chosen at random from among the young present on a site to become the adult at that site in the new generation.

We acknowledge that this simple model probably has few close parallels in the real world. Nevertheless it may usefully force a re-examination of some widely held ideas about migration.

For example, it has been claimed as "intuitively obvious" that in a saturated and time-invariant environment "organisms can never gain any advantage by changing their locations"¹. The schematic illustration presents a counter-example based on the above model

	o	o	o	x	o	o	o
Adults	O	O	O	X	O	O	O
Site labels	a	b	c	d	e	f	g

The environment (represented by the eight sites labelled a to h) here is saturated and time-invariant. In the absence of any migrating mutant like X , and with full survival of stay-at-home propagules, the majority genotype O which keeps all propagules at its own site can perfectly maintain the population. But the 'O' strategy is not evolutionarily stable. The genotype O will be replaced by the mutant X , which keeps only one propagule at home, even though it loses two of its remaining four propagules due to mortality in migration (assumed to be 50%; $p = 0.5$): obviously X has a chance of 1/6 of winning each of sites c and f ; meanwhile, at least against so ill-advised a genotype as O , it certainly retains its base at d . Hence X is certain to become the established type. Of course the particular migration probability of X ($\nu = 4/5$) illustrated here will not itself prove to be the evolutionary stable strategy, or "ess"², except for some special value of the survival factor p . Normally other mutations would supervene, after the spread of X , until finally a migration probability that was evolutionarily stable was approximated.

In general, the one or more ess migration probabilities which the model might have can be determined as follows. The population is imagined to contain two types, using migration fractions ν and ν' . An expression is written for the fitness, w' , of one adult of type ν' . This fitness, or expected number of sites to be gained by offspring, will consist of the chance of retaining the home site plus the expectation of sites to be gained elsewhere by migrant offspring. From this we find the value of ν which has the property that $w' \geq 1$ for all $\nu' \neq \nu$ (mean fitness in the model is unity, so that $w = 1$). The value of ν so found, symbolised ν^* , is unbeatable³ in the sense that any genotype with strategy $\nu' \neq \nu$ will have a diminishing frequency in any mixture.

For the simple limiting case where the number of sites and the number of propagules per parent are large, we find by this method that the ess or unbeatable migration probability is

$$\nu^* = 1/(2-p) \quad (1)$$

Because this formula shows no dependence on the composition of the mixture, stable mixtures are not possible, and the ess can be considered safe against both rare mutations and any massive invasion by a different genotype.

A striking conclusion to be drawn from equation (1) is that even when migrant mortality is extremely high (small p), and the environment offers no vacant sites for colonisation, it is still advantageous to commit slightly more than half of the offspring to migration.

Pre-eminent among the artificialities of this model are: (1) insistence on death and replacement of every parent in each generation; (2) absence of vacant sites (stemming from the deterministic description of the propagation processes); (3) pure parthenogenesis. We now indicate how the model may be extended to encompass such effects, paying particular attention to (2).

Death and replacement of parents

There is one simple and often realistic assumption that allows for perennation of the parents, while preserving the result (1). The assumption is that all parents, irrespective of age, have

Fig. 1 The surface depicted here gives f (the equilibrium fraction of sites occupied) as a function of v (the fraction of offspring that migrate) and p (the relative survival probability for migrants), under the assumptions delineated in the text, for a mean 'brood size' $m = 3$. The contour lines are for constant values of f , spaced at intervals 0.1 apart (that is $\Delta f = 0.1$). On this surface, the trajectory labelled *ess* shows the dispersal strategy that is evolutionarily stable, $v^*(p)$, as a function of p . The *ess* trajectory is to be contrasted with that labelled *M*, which shows the strategy which maximises site occupancy for given p , $\hat{v}(p)$.

some constant probability q to survive and retain their sites into the next season. This corresponds to the so-called 'Type II survivorship curve', which is known to be not far from true for many organisms. For such organisms, both stay-at-home and migrant offspring have their expectations of inheriting a vacant site devalued by exactly the same factor, namely $1 - q$, which consequently cancels itself out of the analysis. (On the other hand, for organisms whose chance of surviving from one year to the next diminishes with age, the *ess* will be age-dependent, if this is biologically feasible. A likely outcome is a 'bang-bang' strategy⁴, with all propagules dispersed until their parent reaches a certain age, whereupon all propagules stay at home.)

Vacant sites

In our simple model, the evolutionary pressure that commits at least half the offspring to migration, no matter how risky migration is, results from an advantage in arranging competitive interactions as far as possible with unlike genotypes. It can be imagined that in nature such a pressure to take risks could cause a wastage that was damaging to the population's chance of survival. This cannot happen in the simple model because its deterministic assumptions keep all sites occupied; to investigate wastage we need some version that relaxes this assumption (2). Such a version may have some bearing on our confidence in models of theoretical ecology in general, because these often take it for granted that the species discussed already have, or will evolve towards, maximal efficiency of resource utilisation.

To this end, we stochasticise the earlier model by assuming the number of propagules produced at any given site is given by a Poisson distribution, with mean equal to the previously constant value m . It follows that the numbers for emigrant and for stay-at-home offspring, and for immigrants, are all generated by Poisson distributions for which the same symbols and expressions as occurred in the simple model are now to be taken as the means. Note that m is the mean brood size and also the variance in brood size, so that the relative magnitude of statistical fluctuations goes as $m^{-1/2}$. The parameter m thus comes to have an important influence, especially when relatively small; when m is large, the present stochastic model tends to revert to the earlier deterministic one.

Now sites can become vacant. Vacancies begin or continue

whenever a site happens to have no surviving stay-at-home offspring and receives no immigrants. Obviously, some migration is essential if extinction is to be avoided, and from the population point of view there will be some level of migration that keeps extinction at furthest reach⁵.

For any specified combination of m , v and p , the system settles to some stable level of site occupancy f (that is f = fraction of sites occupied), with a zero level signifying that extinction is inevitable. This stable level f is given (for $f > 0$) by the implicit relation

$$f/(1-f) = e^{m(1-v)} [e^{mvpf} - 1] \quad (2)$$

For given m , the site occupancy function f defined by equation (2) may be mapped over the unit square of admissible values of v and p : $f(v, p)$ is found to have the form of a smooth promontory (Fig. 1 for $m = 3$), or, for larger m , a squarish headland (Fig. 2 for $m = 10$). In any such figure, for fixed v the occupancy $f(p)$ falls convexly with decreasing p , and clearly must always hit extinction somewhere short of $p = 0$. The smallest p that still allows the population to exist may be shown to occur when $v = 1/m$, that is when just one migrant is dispatched from each site. The concomitant least value of p is given by $p_{\min} = \exp(1-m)$, which is very small for moderate values of m ; slightly larger values of p carry f up to a 'plateau' at a level of nearly complete occupancy. Conversely, for fixed p , the occupancy f as a function of v at first rises (albeit very slightly for large m) to a maximum as v decreases; then, as v decreases further, this is followed by a steepening fall in f , which goes to zero short of $v = 0$.

Thus we may trace out the locus of the strategy, \hat{v} , that maximises the site occupancy f for given p ; this locus moves up a 'cliff', and across a 'plateau' to $p = v = 1$ (Figs 1 and 2). This strategy \hat{v} is that which is 'best for the population'.

This locus of the strategy for maximal occupancy, \hat{v} , is to be contrasted with the locus of the *ess* v^* , which is determined by the method described above. The *ess* migration probability, $v = v^*$, is given by

$$\exp[m(u + vpf)] = \frac{v^2p - vpf(u + vpf)}{v^2p + u(u + vpf)(1 - mv)} \quad (3)$$

Here $u = 1 - v$, and f has the value implicitly fixed by equation (2). The derivation of the results (2) and (3) will be set out

Fig. 2 As for Fig. 1, except that now the mean brood size is $m = 10$. Again the solid contour lines depict constant values of f , from $f = 0$ to 0.9 at intervals of 0.1; the increasingly broken contour lines on the 'plateau' are for $f = 0.99$, 0.999 and 0.9999, respectively. For a more full discussion of Figs 1 and 2, see text.

elsewhere (our work with H. N. Comins); unlike the earlier simple result (1), these equations are made more complicated if age-independent or 'Type II' perennation of the parents is introduced.

The locus of the ess migration fraction v^* , so determined, is shown in Figs 1 and 2. We note that ess migration is always higher than maximum-occupancy migration, although they converge at the two extremes (at perfect and at least-possible survival, $p = 1$ and $p = p_{\min}$). This is true for all brood sizes m . As m is increased towards more usual biological values (from $m = 3$ in Fig. 1 to $m = 10$ in Fig. 2), the separation between the ess and maximum-occupancy loci with respect to v also increases strikingly. This separation results mainly from the way the changing shape of the site-occupancy surface $f(v, p)$ controls the course of \hat{v} ; that is $\hat{v}(p)$ is much more affected by changing m than is $v^*(p)$. The separation between the two loci with respect to f , however, remains very small, even for populations that are on the 'cliff face' of the f surface and hence in some danger of extinction.

In other words, the ess v^* can demand far more migration than is 'best for the population' (\hat{v}), but such excess does not, in this model at least, substantially affect population safety nor create many extra vacant sites that would give other species opportunity to evolve as competitors for the niche. Notwithstanding the small difference in occupancy levels, there is usually strong selection to establish v^* rather than \hat{v} . One incidental consequence of the relatively abundant supply of migrants is that some must overflow from the system and occasionally have the luck to found new populations elsewhere. It therefore seems that our models show, after all, a case where a trait is positively adaptive at more than one level: the ess is best for the genotype, suboptimal at the level of an isolated population, and advantageous in carrying the population to new areas.

Sexual organisms

If the organisms are taken to be sexual rather than purely parthenogenetic, with migration probability depending on the genotype of the offspring, lower values of v^* are definitely expected.

This follows from the observation that our models directly treat the genetic success of a mother. A parthenogenetic offspring has an identical genotype, so that whatever maximises inclusive fitness⁶ for the mother maximises it for the offspring. In contrast, the inclusive fitness of a sexual offspring normally differs from that of its mother, and, in some direct relation to the hazards of migration, will find its optimum at a lower migration rate. Hence there is a conflict of interest between parent and offspring^{7,8}. Its outcome will depend on the biological circumstances: as regards applying a pappus to a seed to make it blow away it is clear that the parent has a strong position; as regards making wing buds become wings in an insect it is much more likely that the offspring can have its preference.

In nature, less migration generally means more inbreeding; such inbreeding reduces the genetic contrast between parent and offspring, and thus tends to diminish the difference between parthenogenetic models and sexual models with offspring-determined migration. Various situations can arise. If males mate before migration in a one-per-site situation, inbreeding is total and the model is again effectively as under parthenogenesis. Unfortunately, the small arthropods which almost meet this extreme of inbreeding and which have a dispersal polymorphism (for example, some mites of the genus *Pygmephorus* (ref. 9 and unpublished results of W.D.H.)) are far from meeting the assumption of fixed unitary sites, being rather exploiters of patchy, ephemeral resources. If inbreeding occurs because males sometimes survive along with a sister, then our one-per-site assumption does not hold.

But if male offspring are assumed always to migrate, then outbred sex can be brought in and the one-per-site feature

retained; moreover, this version may approach realism for some of the many insect species that have free-flying males while females are either wholly flightless or polymorphic for flight. For the simple, non-stochastic version of this model with allele semi-dominance, the ess migration probability for the female offspring is indeed lower than for the parthenogenetic model: in place of equation (1), we now have

$$\begin{aligned} v^* &= 0 & \text{for } \frac{1}{2} > p > 0 \\ v^* &= (2p-1)/(4p-1-2p^2) & \text{for } 1 > p > \frac{1}{2} \end{aligned} \quad (4)$$

The fact that $v^* = 0$ for $p < \frac{1}{2}$ suggests that when this model is made stochastic (along the lines followed previously) the ess may imply situations where the population and the species is dangerously liable to extinction. We are pursuing this open question.

(Roff¹⁰ has used computer simulations to study migration in models which not only have sexual reproduction and multiple adults per site with a density-dependent migration structure, but also have temporal variability in site suitability. It is obvious from the facts of nature¹¹, and is confirmed in both Roff's model and several others^{1,12-14}, that erratic habitat suitability (including local extinction) is an extremely important factor in favouring adaptations for dispersal and migration. More relevant to the present discussion, however, is Roff's demonstration that his ess migration probabilities are considerably lower than those which would keep populations highest and most secure from extinction. Although partly attributable to the workings of sexuality and Mendelian inheritance in Roff's models, this effect arises primarily because there are many adults per site, which changes the calculation of inclusive fitness in such a way as to favour the short term, selfish option of not dispersing.)

It would be satisfying to conclude by listing a few biological illustrations of principles suggested by the models. Unfortunately most of the examples which have come to mind are more in the region of jokes than of reality: they range from *Caulobacter crescentus*¹⁵, whose asexual fission always produces one stalked sessile cell and one motile one that swims away, through the inevitable lemmings and on to the non-first sons in Victorian families who joined the army or went to Australia. Both our simplest model, and the refined versions (1) and (2), support what these examples might illustrate, namely a minimum rule that 'at least one must migrate whatever the odds'. All three examples, however, fail to have fixed sites and, except for *Caulobacter*, fail also in regard to asexuality. There are flight dimorphisms in non-sexual insects (for example, aphids in summer: the tiny sub-cortical beetle *Ptinella errabunda*¹⁶) and probably parallels in some weeds (for example, Compositae)^{17,18}, but in being colonist species these fit badly with the assumptions of fixed sites and of no extinction or recreation of habitats on a large scale. But the fact that colonist plants in arid environments, where perennation of the whole plant (as opposed to survival of its seed) may be hardest to achieve, seem especially inclined to produce actually dimorphic or differently shed propagules with one class buried or otherwise retained beside or under the parent¹⁹ (*Sieglingia decumbens* is the best example in Britain) does at least suggest that a plant's perennating body (or its tubers, corms or the like) should be considered its bid to retain the home site. We expect the investment in such aids to perennation, as opposed to investment in flowers and dispersing seed, to show positive correlation with the chance that seed if produced would end up destroyed or in sites that never could support an adult. For example, the more successful a specialised epiphyte or parasite is at getting its propagules to suitable sites, even when these are objects of intense competition, the more it should produce them. A mistletoe should flower more than an epiphytic orchid; and we should not be surprised to find that weedy perennial species put more net assimilation into seed production than do climax perennial species²⁰. This may be so but is not particularly exciting; other explanations are available. It is not easy to test the quantitative conclusion that,

because $v^* > \frac{1}{2}$ for most values of p , we expect to find at least one-half of net assimilation going into some form of growth or propagule production that extends competition beyond the space that the organism already occupies.

The value of our models lies primarily in their approach and method, in their well-determined conclusions, and in the novelty of having made plain a new reason for the ubiquity of dispersal. We have shown that the habitat does not have to be patchy and of erratic suitability; substantial dispersal is to be expected even when the habitat is uniform, constant, and occupied completely.

letters to nature

Radio emission from a normal HD26676 star

IN the field of an observation of the cluster Abell 478 made with the Westerbork Synthesis Radio Telescope¹ at 21 cm, we have discovered and report here a weak radio source coincident with the 6.2-mag B8Vn star² HD26676. The source positions derived from both the 21-cm observation, and measurements made later at 6 cm, agree within the errors with the AGK3 position of the star (Table 1). The 21-cm data were obtained during a single 8-h observation, while at 6 cm three measurements, each lasting for 10 h, were made over a period of 6 weeks. There is no significant indication of variability from the three flux densities derived at 6 cm (Table 2). The global 6-cm flux density, as well as the position in Table 1, were obtained by combining the three observations in a single map.

Polarisation (linear and circular) is less than 10% of the total intensity at 21 cm and less than 20% of that at 6 cm. The radio source is unresolved at both wavelengths, which sets an upper limit (in right ascension) of about 4 arcs to the angular size. No radio emission coincides with the reflection nebula associated with the star³ at a level of about 2 mJy per beam (area about 1 arc min²) at 21 cm and about 1 mJy per beam (area about 0.1 arc min²) at 6 cm.

Although the optical and radio positions agree, within the errors, we must consider what the probability of a chance coincidence is. The area enclosed by the 6-cm position errors is about 2×10^{-6} deg². The density of stars brighter than 8 mag (ref. 4) (we assume that anyone finding a radio source close to such a star would be prompted to investigate the possibility of association) is about 1 deg⁻², suggesting an *a priori* probability of 2 in 10^6 that the coincidence occurred by chance. While this is reasonably small, thorough identification work has been

done on nearly 1,000 radio sources observed with Westerbok at 21 cm (see ref. 5 and refs therein), and one other radio position agrees with that of a 13-mag star. Nevertheless, we conclude that the star and radio source are probably related and now consider the consequences of this fact.

Assuming the source did not vary during the 10 months separating our two sets of observations, the flux densities in Table 2 give a spectral index between 6 cm and 21 cm of $\alpha = -0.8 \pm 0.2$ (where flux density is proportional to frequency α). This qualifies HD26676 as a radio star according to the definition of Hjellming *et al.*⁶: if the source has not varied, its radio spectrum clearly indicates that the radiation is not the result of free-free emission from a surrounding nebula. Like several of the other radio stars (such as β Per and β Lyr), HD26676 is of an early spectral type. At a distance of 126 pc (ref. 3) its 21-cm luminosity is 2×10^{10} W Hz⁻¹. The radio power between 1 GHz and 10 GHz (assuming a constant spectral index) is 8×10^{26} erg s⁻¹, a value typical of the 'quiet' state of radio stars.

Table 2 Measured radio flux densities

Wavelength (cm)	Mean date	Flux density (mJy)
6	6.5 February 1977	5.8 ± 1.2
6	21.9 January 1977	3.3 ± 1.1
6	27.9 December 1976	4.3 ± 1.1
6	(combined)	4.1 ± 0.6
21	12.8 February 1976	11 ± 2

In several respects HD26676 differs from other radio stars. Its spectral index is negative, while that of radio stars in their quiet state is usually positive. But there is evidence that the radio flares must be non-thermal⁸ and in several cases, notably Sco X-1 (ref. 9), the spectral index is generally negative. Of course, Sco X-1 is predominant as an X-ray star, and the SAS-3 observation of Abell 478 (ref. 1) enables one to put a limit on any X-ray emission from HD26676. H. W. Schnopper (personal communication) has estimated that the count rate cannot exceed one-third of that from Abell 478. This means that the 2-11-keV luminosity of HD26676 must be less than a few times 10^{31} erg s⁻¹ (epoch 1976.9). This is considerably less than the luminosity of typical X-ray stars such as Sco X-1, Cyg X-1 and Cyg X-3, all of which are also radio sources.

Table 1 Optical and radio positions

Observation	Right ascension (1950.0) (h min s : s)		Declination (1950.0) (° ' " ± ")	
Optical*	04 10	50.11 ± 0.01	10 05	11.54 ± 0.2
6.0 cm	04 10	50.19 ± 0.11	10 05	04 ± 9
21.2 cm	04 10	50.14 ± 0.15	10 05	07 ± 16

*The position given is corrected for proper motion to 1977.0

The most important difference between HD26676 and all other radio stars is the fact that it is not known to be either a binary system or a variable star. Most models of the radio emission make use of mass exchange between stars in the system⁷. For this reason HD26676 could be a critical test case for emission mechanisms. If further observations confirm the radio-optical association and its non-binary character, it would provide an important constraint for future models.

We thank Dr C. Jaschek of the Centre de Données Stellaires, Observatoire de Strasbourg, for references for HD26676. Enhanced metal depletions and interstellar H₂ abundances

THE OAO 3 Copernicus ultraviolet satellite has provided important new data on the abundances of elements in the interstellar gas in the direction of many O and B-stars along lines of sight of low optical depth¹⁻⁴. This information may make it possible to choose between the following theories of molecular hydrogen formation in interstellar clouds: (1) physical adsorption of H-atoms on to cold dielectric grains and their subsequent recombination and desorption⁵; (2) H₂ recombination on graphite grains⁶; and (3) hydrogen recombination by non-activated chemisorption on transition metal grains⁷. Indirect methods of testing the above theories are essential because there is a glaring lack of experimental data, especially for processes (1) and (2). Also, it does not seem possible that in the near future radio astronomers will be able to measure the abundances of the various hydrogen ions (such as H₂⁺ and H₃⁺) that the above theories predict⁸.

In view of the fact that the catalytic production of H₂ can take place in the laboratory⁹, it probably occurs in the interstellar medium because the temperatures of metal grains are about an order of magnitude hotter than dielectric ones¹⁰. An examination of the depletion of interstellar elements from the gas phase may ultimately be able to discredit or lend credence to this theory. Consider Table 1, which lists the interstellar depletions with respect to solar system abundances ($\delta = \log(N/N_H) - \log(N/N_H)_\odot$) along lines of sight to ζ Oph (ref. 2), o Per (ref. 4), and λ Sco (ref. 3) for certain key elements—carbon, oxygen, silicon, and iron. Towards ζ Oph and o Per, where the

visual extinction $A_v \approx 1.0$ mag, the fraction f of hydrogen that is in molecular form is between 0.5 and 0.7, while towards unreddened λ Sco, $f \sim 10^{-7}$. There seems to be a weak correlation between iron and silicon depletions and H₂ abundances. In contrast there seems to be no noticeable relationship between the amounts of carbon and oxygen depleted from the gas phase and the amount of gaseous H₂ detected. Since it is commonly assumed that process (1)—the physical adsorption of hydrogen—is the primary mechanism for H₂ production, one might have expected to find enhanced carbon and oxygen depletions with the higher abundances of H₂. The reason for this preconceived notion is the assumption that the cold dielectric grains where this process is thought to occur are mainly silicate core particles with heavy mantles of C-N-O 'ices'⁵.

These conclusions are partially reinforced by an examination of depletions in high-velocity clouds. Barlow and Silk¹¹ have shown that there is a systematic depletion of iron and silicon with gas velocities towards unreddened stars: the higher the velocity, the lower the amount of depletion. They make a strong case that this is the result of the sputtering of refractory grains in interstellar shocks. It is interesting to note, however, that the graph of the depletion factors for iron and silicon plotted against the logarithm of gas velocity has the same characteristic shape (but opposite slope) as a plot of $\log N_H$ (cm⁻²) against $\log v$ (km s⁻¹). This effect may be statistical in that Barlow and Silk used data from only seven stars. It is also reasonable to assume that this pattern is not a coincidence and that higher gas velocities always correspond to an increase of iron and silicon in the gas phase and a decrease of atomic hydrogen, as explained by their 'snowplow' model¹¹.

An examination of the data for these seven stars¹¹⁻¹³ shows that although there is a good correlation between the δ s and gas velocities, there is only a very weak correlation between the δ s for iron and silicon and the values of f . For example, for the low-velocity component of μ Col (ref. 12), $\delta(\text{Fe}) = -1.8 \pm 0.2$ and $f \approx 4.5 \times 10^{-5}$, while for the higher-velocity component, $f \approx 6 \times 10^{-7}$. Unfortunately, for HD74455 (ref. 13), $\delta(\text{Fe}) \sim 0.1$ while $f \sim 4 \times 10^{-5}$. Part of the problem is that towards all these unreddened stars, $10^{-4} < f < 10^{-7}$, and a small error in observation or reduction can produce a correspondingly much larger error in f . Also, these stars may have fairly recently undergone heating by interstellar shock fronts, producing large deviations from equilibrium abundances. Thus, studies attempting to correlate $\delta(\text{Fe})$ with H₂ abundances should confine themselves to low-velocity clouds of appreciable ($A_v \approx 1.0$ mag) extinction.

If we do accept the possibility that there is a direct correlation between the amount of H₂ being produced and the amount of iron and silicon in the grains, we are still left with two alternatives. First, some of the H₂ may be formed by means of catalytic reactions on the surfaces of iron grains (process (3)). Although nothing in the above analysis proves this conclusively, nothing contradicts it either. Second, H₂ may be produced by process (1) on cold, silicate grains through the mechanism of physical adsorption. Although it may be possible for reasonably pure iron grains to exist in the interstellar medium by virtue of the fact that metallic iron will condense out of a hot gas before any of its compounds, the same cannot be said for silicon. Studies of the condensation temperatures of compounds and elements¹⁴⁻¹⁶ show that pure silicon is an unlikely possibility. Instead, silicon forms such compounds as CaAl₂Si₂O₈, Ca₂SiO₄, and Mg₂SiO₄¹⁷. Thus, for every atom of silicon that is depleted, there is an average of 3-4 oxygen atoms. As oxygen is about 21 times more abundant cosmically than silicon¹⁸, there is still

Table 1 Interstellar depletions of elements

Star	$E(B-V)$ (mag)	$\delta(C)$	$\delta(O)$	$\delta(Si)$	$\delta(Fe)$
ζ Oph	0.32	-0.87 to -0.54	-0.68 to -0.49	-1.88 to -1.38	-2.05 to -1.89
o Per	0.32	-1.65 to -0.43	-2.70 to -0.59	-2.13 to -1.82	-2.39 to -2.14
λ Sco	0.03	+0.2 to -0.9	-0.7 \pm 0.1	-1.1 \pm 0.1	-1.3 \pm 0.2

plenty of oxygen left to be incorporated into extensive 'ice' mantles and still agree with the interstellar depletions listed in Table 1. Hence, nothing in Table 1 contradicts the possibility of process (1). (As for process (2), nothing can be said at this time since there is a strong possibility that crystalline graphite cannot be produced in the interstellar medium^{19,20}.)

Observations of interstellar depletions may one day be able to decide how H_2 is produced in interstellar clouds. At present all that can be said is that neither process (1) or (3) can be dismissed without further consideration. It is hoped that this paper will stimulate additional research.

Interstellar grains as possible cold seeds of life

As long as entropy ceases to play any part in equilibria when the temperature approaches absolute zero, all exothermic reactions—up to the formation of the most complex biopolymers—become thermodynamically profitable. In such conditions the reaction rate starts to play a decisive part in the observability of chemical transformations. According to classical views (Arrhenius law) all reactions should completely stop when $T \rightarrow 0$ and therefore the cold synthesis of biologically active substances is absolutely excluded. The phenomenon of a low-temperature limit to chemical reaction rates found recently, however, in the studies of radiation-induced polymerisation of formaldehyde¹⁻³, showing the existence of chemical reactivity even at $T \rightarrow 0$, obviously caused by quantum-mechanical molecular tunnelling, makes it possible to combine complete suppression of the entropy term in equilibria with an observable rate of exothermic chemical reactions, for example, of chain polymerisation (or any other integration of molecules) induced by light or ionising radiation. Thus molecular tunnelling suggests the possibility of a cold pre-history of life¹⁻³.

The possibility of synthesising rather complex molecules under the combination of deep cosmic cold and various radiations of cosmic origin was recently proposed by Wickramasinghe⁴⁻⁶ and Hoyle and Wickramasinghe⁷. Basing their argument on the properties of galactic nebulae in the infrared wavelength region they concluded that formaldehyde undergoes polymerisation in interstellar space with the formation of polyoxymethylene and even of polysaccharides.

As discussed elsewhere⁸, the only possible mechanism of interstellar formation of such complex substances must be molecular tunnelling. From the results given in refs 1-8 one can assume that the grains of interstellar dust clouds serve as cold seeds of life.

Interstellar chemical reactions have attracted the interest of astronomers, physicists, chemists and biologists (see refs 9-15).

Attention has been paid mainly to the gaseous reactions in interstellar clouds as well as to the reactions at the surface of grains. Most data concerning the formation of complex n -atomic molecules for $n \leq 5-9$ were explained by the mechanisms of bimolecular ion-molecule, or radical-radical, or radical-molecule interactions.

All authors, however, agree that the generally accepted mechanisms listed above are insufficient and unsatisfactory for $n \geq 5-9$. So clearly, these mechanisms should not be applied to the formation of polyoxymethylene and more complex compounds.

It seems necessary to consider interstellar grains as possible cold seeds of life, with chemical reactions in the bulk of these grains as a very important stage of prebiotic evolution. The idea of a very significant role of reactions in 'dirty-ice' mantles of grains in the formation of quite complex molecules (up to amino acids) was put forward and defended by Greenberg (see refs 11, 13, 16). He regards as a main process leading to the integration of molecules the recombination of ultraviolet-produced radicals and other active centres assuming that such processes can lead to the explosion of grains once the over-critical concentration of active centres is reached. Besides emphasising that the action of any permanent external ultraviolet source can lead only to saturation in the yield of radicals rather than to their over-critical concentration^{8,17}, one should remember that the recombination of radicals cannot form more complex products than can the other mechanisms mentioned here. I do not discuss here the role of shock wave-induced polymerisation and polycondensation of solids (up to the transformation of amino acids in polypeptides) we have observed¹⁸⁻²⁰.

The cold pre-history of life, of prebiotic evolution in interstellar clouds postulated here is based on several main points. (1) The formation of complex molecules—up to the biopolymers—proceeds in the 'dirty-ice' mantles of interstellar grains in diffuse or dense clouds at very low ($T \sim 10-20$ K) temperatures. The decisive part in such formation is played by exothermic (particularly chain-type) processes of addition and polymerisation proceeding by molecular tunnelling.

(2) Integration of molecules in surface regions of clouds is ultraviolet-initiated. As shown elsewhere⁸, the appearance of long chains ($\nu \gg 1$) of chemical transformations is possible in such conditions only if the duration of an elementary act of continuation of chain $\tau_E \ll R_{act} \tau_{uv}$, where $R_{act} \sim 10^{-3}$ to 10^{-2} is the saturated concentration of active centres, that is, the time spent by each molecule in an active state under the external ultraviolet-irradiation. $\tau_{uv} \sim 100$ yr is the characteristic time between two successive ultraviolet absorptions by any molecule of the grain. Thus for the development of long chains $\tau_E \ll 0.1-1$ yr.

(3) Integration of molecules in the depths of clouds can be initiated only by long-range cosmic protons. As the characteristic time between two successive interactions of such protons with any molecule of the grain $\tau_p \sim 3 \times 10^9$ yr is 10^3-10^4 times longer than the life-time of dust clouds τ_{cl} limited by their gravitational collapse or by cloud-cloud collisions (10^6-10^7 yr)^{4,14} the accumulation of active centres in the depths of clouds does not reach saturation. Therefore, the development of chains of reactions requires the much less stringent condition: $\tau_E < (1/\nu) \tau_{cl}$ and one can expect the formation of more complex molecules, and the occurrence of much more advanced prebiotic evolution in the depths of clouds rather than at their surfaces and in the interstellar gas.

(4) The equilibrium chemical composition of cold interstellar dust can be obtained by relatively simple calculations under the assumption that entropy factors can be neglected and that the whole totality of chemical reactions leads to the formation of the system of monomers with a minimum possible enthalpy (for the given balance of abundances of various elements).

The possibility of existence of some unsaturated H, C, N, O (and also S, P)-containing monomers (with multiple inter-

atomic bonds) in such equilibrium dust would automatically mean also the possibility of exothermic polymerisation of such monomers (like the case of polymerisation of formic acid and methanimine with formation of glycine mentioned in ref. 21), and molecular tunnelling opens the route of such polymerisation valid even at $T \rightarrow 0$.

In this way the possibility of energetically profitable formation of unsaturated monomers at the natural balance of elements' abundances would clearly constitute a serious argument in favour of the hypothesis of cold prebiotic evolution in interstellar grains.

(5) When the cloud collapses and a new hot star is created in its centre, the flattened protoplanetary disk formed from the remnants of the cloud continues to be cold. The temperature does not rise during either the consequent accretion of dust particles with the formation of planetesimals (including comets) or the agglomeration of most of planetesimals into the planets²¹⁻²⁷. This makes it possible that the formation of complex polymer molecules in cold interstellar dust can provide a real cold pre-history of life rather than simple accumulation of negative entropy. The molecules formed can reach such a high degree of complexity that they are even able to display the simplest biological functions as soon as the new star begins to heat its own planets and thus sharply increases the rate and variety of chemical reactions.

Muon catalysis of hot fusion

THE idea of muon catalysis of cold fusion dates back nearly 50 years¹⁻³, but the death blow to the technique was given by Jackson⁴. It has been revived by Tan⁵ in connection with fusion in inertially confined pellets and his idea is sufficiently important to warrant further investigation. Our calculations suggest that Tan's estimates are unjustifiably optimistic and so there is no possibility of achieving an energy gain.

The basic reactions are

and the corresponding dd and tt reactions which have a rather

lower probability. We assume, following Tan, that the pellet is totally ionised, and for definiteness consider a 0.5-cm radius pellet at a temperature of 10 keV and solid density. The reactions then occur in flight with a total rate of about 10^9 s^{-1} .

The method avoids the formation of $(\mu\text{He}_4)^+$, which normally terminates the catalysis chain for the following reason: the recoil $(\mu\text{He}_4)^+$ moves off with an energy of 3-4 MeV. Although it is travelling through a dense medium, the usual energy loss mechanism (ionisation of ordinary atoms) is no longer available to it. The only mechanisms available in a plasma are elastic scattering by the Coulomb force and ionisation of the $(\mu\text{He}_4)^+$. Using standard techniques⁶ we find the corresponding rates to be 10^7 s^{-1} and 10^9 s^{-1} (we have rounded off all rates to the nearest order of magnitude). In other words, stripping of the muon is very probable, and it would thus be able to take part in further fusions.

Unfortunately this is irrelevant for the inertial confinement as proposed by Tan. If the confinement time is 10^{-9} s , and the reaction rate 10^9 s^{-1} , on average each muon would catalyse one reaction, hence the occurrence of R_c (the catalytic chain ratio) in equation (5) of ref. 5 is erroneous.

The cost of producing a useful muon (that is, one stopping in the pellet) has been grossly underestimated by Tan. According to Tan e_μ (the energy required to produce one muon) lies between 10^9 and 10^{10} eV , and x_μ (the fraction stopping in the target) between 10^{-4} and 10^{-2} , so that e_μ/x_μ lies between 10^{11} and 10^{14} eV per useful muon. The higher value of e_μ is taken from Jackson who optimistically proposed a ratio of proton beam energy to input electrical power of 0.2 (for TRIUMF, this ratio is ~ 0.01) and assumed that every muon produced was available to catalyse a fusion reaction. In addition, however, only a very small fraction of muons can be focused into a useable beam.

It is more useful in the situation being discussed here to refer to values of e_μ/x_μ that are obtained in today's meson factories, with beams designed to optimise muon stopping rates in small targets. In the standard technique, pions from a target placed in the proton beam are collected in a long ($\sim 10 \text{ m}$) magnetic channel which confines them and their decay muons. The latter emerge from the channel exit in a very crudely focused beam; obviously they cannot be sharply focused as their source is fairly large radially and very long axially. If we take as typical 'state of the art' values, an accelerator input power of $2 \times 10^{25} \text{ eV s}^{-1}$ (TRIUMF: 100 μA at 500 MeV) and a μ stopping rate of $10^5 \text{ g}^{-1} \text{ s}^{-1}$ (SIN: 100 μA at 500 MeV) then for a 0.5-cm radius pellet of density 0.71, e_μ/x_μ is $5.4 \times 10^{21} \text{ eV}$. In fact, as we show below, the stopping rate in an ionised pellet would be very much smaller.

The final objection is the most serious. Whereas it is true that the capture reaction

has a rate of 10^{12} s^{-1} in a solid, it is not true in a plasma, even at solid densities. Using Thomson's classical model⁶, the capture rate is $\sim 10^3 \text{ s}^{-1}$, if we assume the plasma to be totally ionised. In fact, the plasma will be about 99.98% ionised, and the remaining atoms could be reasonably effective in capturing mesons. To estimate this rate, we assume that an atom has the same capture rate in a plasma as would in a solid, and multiply the solid rate by the effective density of atoms. This gives a rate of 10^8 s^{-1} , which in itself is a gross overestimate as capture in a solid occurs only for very slow muons. This is not incompatible with the Saha equation: the only significant population of muons will be in the 1s level, and, by the above arguments, the reaction time for capture into the 1-s level is very much longer than the operative timescale of 10^{-9} s .

The same point may be made in slightly different fashion: Tan assumes that the incident muons have an energy of 4 MeV and are stopped in the first 10^{-3} m of the pellet. In fact, the mean free path will be $\sim 80 \text{ cm}$, so if the pellet is pre-ionised, it will be totally transparent to muons. Further, we note that

the pellet will be transparent to the reaction products (4 MeV α 's and 14 MeV neutrons) so no heating of the pellet will occur.

We thank Dr P. A. Redhead for bringing Tan's paper to our attention, and Dr C. K. Hargrove and Dr H. Mes for discussions.

Water-promoted oxidation of carbon monoxide over tin(IV) oxide-supported palladium

CATALYTIC oxidation of CO, both by O₂ and by nitrogen oxides (NO_x), is of considerable relevance to the removal of toxic CO and/or NO_x from exhaust gases. Certain applications such as automobile exhaust control in cold-start conditions, and the removal of CO from tobacco smoke by use of a catalytic filter, demand not only catalytic activity at moderately low temperatures, but also effectiveness in the presence of water vapour. The low-temperature activities of most catalysts are at best (for example precious metals) partially destroyed, or at worst (for example base metal oxides) totally destroyed by poisoning due to water vapour. The results presented here demonstrate that, not only is the low-temperature activity of the Pd-SnO₂ system not poisoned by water vapour, but rather its presence causes a marked enhancement in activity for the oxidation of CO both by O₂ and by NO.

The catalytic activity of SnO₂-supported palladium for the oxidation of CO both by O₂ (refs 1, 2) and by NO (ref. 3) has previously been shown to be considerably higher than that predicted from purely additive or metal dispersion considerations. This synergism has obvious relevance to potential applications where precious metals are supported on oxide carriers, a topical example being the oxide wash-coats used to 'key' precious metals to the honeycomb monoliths developed for the catalytic control of exhaust gases. These previously reported catalytic data for CO oxidation over Pd-SnO₂ were obtained using anhydrous feed gases, and here we report the effects of adding water vapour.

Samples of 1.8% Pd on SnO₂ and 5.8% Pd on SiO₂ were prepared by non-exhaustive ion-exchange sorption, from Pd(NH₃)₄²⁺ solution, on to 36-72 B.S.S. mesh SnO₂ (ref. 4) and SiO₂ (BDH, pretreated with 1 M HNO₃ and exhaustively washed with water) gels respectively. Thermal activation (5 h at 450 °C in air) and reduction (2 h at 150 °C in 30% CO in Ar) were carried out in the catalytic reactors using anhydrous gases. Specific surface areas after this treatment were 40, 70 and 230 m²g⁻¹ for SnO₂, Pd-SnO₂ and Pd-SiO₂ catalysts respectively. With the exception of the CO-O₂ reaction over Pd-SnO₂ which, because of the low weight required was performed at 60 °C in a 2-mm internal diameter stainless steel U-tube, the previously described⁴ glass reactor assembly was used. Water vapour of various concentrations was admitted to the feed gases by bubbling through H₂SO₄ solutions of

known concentrations. Gas chromatographic analyses of the products of the CO-O₂ and CO-NO reactions have been described (refs 5 and 6 respectively). Catalytic rate data for the CO-O₂ reaction are quoted in terms of CO conversion for a feed of 5% CO in air at 100 cm³min⁻¹, and those for the CO-NO reaction in terms of NO conversion (both to N₂O and to N₂) for a feed of 14% NO in CO at 30 cm³min⁻¹.

Typical steady-state (16 h) conversions for the CO-O₂ reaction over the Pd-SnO₂ catalyst (0.25 g) at 60 °C using anhydrous feed gases gave values ranging from 0.7 to 1.2% CO oxidation (four experiments). Introduction of water vapour at a partial pressure of 22 mm Hg caused, after a 4-h conditioning period, an increase in conversion to 10-13%, and this remained constant over a further 24 h period. This order-of-magnitude increase was essentially independent of the water concentration within the partial pressure range of at least 5-22 mm Hg. At p_{H₂O} < 1 mm Hg the enhancement in activity was less than that at higher pressures, but even at p_{H₂O} = 0.1 mm Hg the steady-state activity was still a factor of about 5 higher than the 'anhydrous' rate. Water vapour partial pressures above 22 mm Hg were not investigated because of problems of condensation in the apparatus. The effect of removal of water from the feed gases was to cause only a very slow return to the 'anhydrous' rate. For example, in an experiment in which the 'anhydrous' and 'wet' CO oxidations were 0.7 and 11.7% respectively, removal of the water vapour for 16 h only decreased the conversion to 3.1%. This slow reversibility is presumably attributable to the low rate of dehydration/dehydroxylation of the hydrated surface (see below) at 60 °C.

In contrast to these findings, the steady-state CO oxidation activity of SnO₂ at 170 °C was found to be totally destroyed, and that of the 5.8% Pd-SiO₂ at 140 °C reduced by a factor of >0.2, by the introduction of 22 mm Hg water vapour pressure to the gas feeds.

The presence of water vapour also caused a comparable enhancement in activity for the CO-NO reaction over a 1.0 g bed of the Pd-SnO₂ catalyst at 130 °C. A steady-state (16 h) 'anhydrous' NO conversion of 0% to N₂ and 32% to N₂O was, after the introduction of water vapour at 22 mm Hg partial pressure followed by a 4-h conditioning period, increased to 34% to N₂ and 51% to N₂O. This increased activity remained constant over a further 24 h period although, in contrast to the CO-O₂ reaction at 60 °C, removal of the water vapour resulted in a much more rapid (<16 h) return to the 'anhydrous' rate. This is presumably attributable to a more rapid dehydration/dehydroxylation of the hydrated SnO₂ surface at the higher temperature. In the case of the CO-NO reaction it is apparent that, not only does water vapour increase the overall reaction rate, but it also influences the selectivity towards the preferred (from the pollution control viewpoint) complete reduction of the NO to N₂.

Previous investigations into the CO-O₂ reaction over Pd-SnO₂ have shown strong evidence that the synergistic catalytic effect is attributable to spillover of CO in an activated form from the Pd to the SnO₂ surface³. The results presented here suggest that the role of the water vapour is to increase this spillover rate, as the actual catalytic oxidation rates over both pure SnO₂ and over Pd supported on an 'inert' oxide are decreased by the presence of water vapour. A probable explanation for this effect is that water molecules produce hydroxylated sites on the SnO₂ surface which act as chemical bridges to assist spillover of the Pd-activated CO. It has been observed that adsorbed proton acceptors (reported water and alkanols) can assist spillover of activated hydrogen from precious metals on to oxides⁷. But, the mechanism of Pd-activation of CO before its spillover is not yet clear. In the case of hydrogen spillover the activation process

can be readily explained in terms of dissociative chemisorption to produce hydrogen atoms. Even if dissociation were to occur during CO adsorption on Pd, which is unlikely on the basis of current evidence⁸, it is difficult to envisage how this process could explain the above observations.

Windscale effluent in the waters and sediments of the Minch

A SYSTEMATIC intrusion of water of high ^{137}Cs content into the north-eastern North Sea has been reported by the German Hydrographic Office¹. Jefferies *et al.*² later confirmed that a stream of water rich in radioactive caesium from Windscale passes northwards through the Hebridean Channel, around the north of Scotland and into the North Sea. Although the circulation pattern with respect to ^{137}Cs has been significantly refined in recent reports³ and from German data for 1975 (ref. 4) and 1976 (Kautsky, personal communication) little attention has been paid to the status of other radionuclides in this stream. Such a study offers, however, an excellent opportunity of looking at the geochemical discrimination between, for example, ^{137}Cs and the transuranic α -emitting nuclides; it seemed also that an examination of the changes of the ratio of ^{134}Cs to ^{137}Cs during this passage would give a good basis for estimation of the travel time. As a part of the Flex Programme (Fladen Ground Experiment—part of Jonsdap 76 international programme on the interplay of environment and a plankton bloom) in the North Sea in May–June 1976, we collected a series of sediment, water and biota samples for that purpose. We report here our analyses of samples from a large-volume water station and a 21-cm diameter sediment core taken in the Minch, 27 May 1976.

Our sampling procedures are described elsewhere^{5,6} as are our analytical procedures, and their performance in a variety of IAEA- or NBS-organised intercomparison exercises^{7–10}. Table 1 shows the nuclide analyses so far completed on 55-litre unfiltered water samples from four different depths, together with comparable analyses of alternate sections of the sediment core taken at the same time. For water column and sediment, the inventory inferred for each nuclide from the data presented, and the mean ratios of selected nuclide pairs are shown.

It should be noted that both water and sediment collected anywhere in the oceans today may be expected to contain ^{137}Cs , $^{239,240}\text{Pu}$, ^{238}Pu or ^{241}Am , as a result of their dissemination in world-wide fallout. The analysis of these nuclides and the use of their distributions to infer rates of marine processes are major activities of our laboratory^{11,12}. ^{134}Cs , however, was only a trivial component of world-wide fallout, about $0.25 \times 10^6 \text{ Ci}$ produced¹³, mostly before 1958, compared with $34 \times 10^6 \text{ Ci}$ ^{137}Cs ¹⁴. The ^{134}Cs present in environmental samples collected since 1970 is certainly to be attributed to some aspect of the nuclear fuel cycle. In the case of other nuclides, similar inferences can be drawn either from their presence in amounts far exceeding those to be expected from fallout

delivery measurements, or from departures in their relative proportions from the ratios found in fallout.

The data tabulated indicate Windscale effluent as the preponderant source of the nuclides in the water column and as a major contributor of those in the sediment. This is shown by the large amounts of ^{134}Cs , and by its ratio to ^{137}Cs : recent data referring to this phenomenon at Windscale have not been published, but the ratio ^{134}Cs to ^{137}Cs approximated 0.23 in 1970², 0.18 in 1971², 0.17 in 1972², 0.19 in 1973¹⁵, 0.24 in 1974³ and 0.18 in 1975³.

Comparison of the water and sediment inventories of ^{137}Cs , ^{90}Sr and $^{239,240}\text{Pu}$ in the Minch location (Table 2) with delivery estimates from fallout at this latitude¹⁶ strongly support the Windscale conclusion in respect of the source of a major fraction of these inventories. A similar conclusion is reached from comparison of the water ratios $^{137}\text{Cs}/^{90}\text{Sr}$ and $^{238}\text{Pu}/^{239,240}\text{Pu}$ with those to be expected at that latitude from fallout. The $^{238}\text{Pu}/^{239,240}\text{Pu}$ ratio of 0.14 is understandable in terms of the reported discharge value from Windscale of about 0.2 for 1971–73 (ref. 17).

Accepting that the major source of the nuclides measured was the Windscale effluent, a variety of hydrographic and geochemical conclusions can be argued. First, from the change in ratio ^{134}Cs to ^{137}Cs in the water, travel time from the Irish Sea can be estimated. ^{134}Cs has a half life of 2.06 yr compared with 30.1 yr for ^{137}Cs . Making the assumption that the two caesium isotopes are not discriminated in ocean circulation, and less satisfactorily that a ratio of 0.24 characterised the source term, then from the ratio 0.144 observed at the Minch it is concluded that the travel time from the Windscale pipeline to the Minch was about 1.6 yr. If source term ratio had been closer to 0.18, as might be argued from other data^{2,3}, then a travel time closer to 0.7 yr would be concluded. Neither calculation is at first sight compatible with the very slow passage times that were suggested by Jefferies *et al.*² for transit from Windscale to the North Channel. An appreciable fraction of the total travel time may have been spent in the Irish Sea, and this is, in fact, indicated by the mean ratio 0.20 reported³ in plaice and *Nephrops* from the northern Irish Sea in 1974. In the Irish Sea, reduction of the ^{134}Cs to ^{137}Cs ratio by mixing with older, lower ratio water from Windscale could be significant, especially considering the ratios reported for 1971–1973 releases: reduction by mixing with fallout ^{137}Cs free of ^{134}Cs is suggested to be insignificant by the expected fallout ^{137}Cs concentration in coastal water, about 0.2 pCi l^{-1} at most by 1973–1974¹¹ and little more than 0.1 by 1976 (Kautsky, unpublished).

The most likely solution to the dilemma caused by the different transit times derived from this and from Jefferies' work² is that we are seeing the net effect of two (at least) processes. First, the mixing process within the Irish Sea and, second, the outflow from the Irish Sea into the coastal current travelling northwards parallel to the west coast of Scotland. The first process may be very much slower than the second so that the net effect may be controlled more by the mixing times within the Irish Sea. Additional support for this two-component process comes from comparison of our ^{137}Cs concentrations in the Minch in May 1976 with the values about $4\text{--}5 \text{ pCi kg}^{-1}$ for July 1974³. Our values of $4.7\text{--}6.5 \text{ pCi kg}^{-1}$ are not significantly different from the values measured 1.8 yr earlier. As these show little difference, it is arguable that May 1976 samples from the Minch have not begun to be affected by the rise in Windscale ^{137}Cs discharge described by Hetherington³ in 1974. So a net transit time of 2 yr could be composed of a term of 1.8 yr in the Irish Sea and 0.2 yr in the coastal current between North Channel and the Minch. Additional evidence that the coastal current labelled with radionuclides originating from Windscale is moving rapidly, comes from preliminary measurements of the $^{134}\text{Cs}/^{137}\text{Cs}$ ratio in water, also collected in May 1976, in the North Sea between Scotland and Norway. At this location (58° 25.5'N, 0° 03.4'E), the measured ratio of 0.14 is indistinguishable from the ratios measured in the Minch.

Second, from comparison of the inventory of radiocaesium in the sediments of the Minch against the estimated total delivered to the area, with the same relation in respect to fallout, some

§By α spectrometry after radiochemical separation; curium isotopes accompany Am in our procedure. No ^{242}Cm was observed, and ^{244}Cm was present only in the amount (about 1 count per day) added as an impurity in our ^{243}Am yield monitor.

conclusions can be drawn about the geochemical behaviour of Windscale radiocaesium. Noshkin and Bowen¹⁶ reported about 7% of fallout ^{137}Cs delivery was found in very shallow-water sediments of Buzzards Bay; using more recent data to interpolate between Buzzards Bay and the 200-m cores from slightly further north, one might predict only 5–6% of fallout in sediment cores under 100 m of water.

Estimating the Windscale-derived delivery of Cs nuclides to the Minch is difficult at best, and made even more so by the fact that Windscale release data for ^{137}Cs have been published only for the years 1957–67¹⁴ and 1972–73¹⁷. Using the data available, and extrapolating to estimate an annual average, ^{137}Cs release of 15,000 Ci for 1968–71, yields a release estimate, through 1973, of 156 kCi, which, divided by the area of the Irish Sea (after Hetherington¹⁷), corresponds to a ^{137}Cs delivery of 6.2 Ci km⁻². The fraction of Windscale ^{137}Cs reaching the Minch can be estimated by comparing the water column inventory (or the total inventory, water plus sediment) in Table 1 (579 or 634 mCi km⁻²) with the mean Area A water column inventory of 2.40 Ci km⁻² in 1974¹⁷. This comparison is consistent with the 2 yr travel time, from Windscale to the Minch, that we inferred above from the ^{134}Cs to ^{137}Cs ratio and ^{137}Cs concentration data. If the shorter, 0.7 yr, travel time were correct, then the inventory for comparison should be that, in the Irish Sea, of late 1975, requiring use of data

not yet available. One arrives, therefore, at the conclusion that the Minch 'sees' about 25% of the ^{137}Cs delivered by Windscale to the Irish Sea, and this should have represented, by 1976, at least 1,550 mCi km⁻² ^{137}Cs delivery to the Minch, and possibly more. The 3.5%, or less, of the inferred Minch delivery of ^{137}Cs found in the sediments may differ significantly from the 5–6% predicted for fallout ^{137}Cs , but we do not believe that the quality of the estimated values justifies this conclusion. If we were to take it seriously, we would argue that it shows either a systematic difference in properties of the Minch sediments, or the effect of isotope exchange at the much higher ^{137}Cs specific activities found in Windscale effluent. Certainly the observations do not suggest the Windscale caesium as either more or less reactive than that from fallout.

Third, from comparison of the ratio of the water column inventories of ^{137}Cs and $^{239,240}\text{Pu}$ with their ratio in the north-eastern Irish Sea conclusions can be drawn about the long-range trajectory of Windscale plutonium in British coastal waters. Calculated inventories of soluble $^{239,240}\text{Pu}$, and of ^{137}Cs , in the waters of the Irish Sea are available¹⁷ for both 1973 and 1974. From these it seems the mean ratio $^{239,240}\text{Pu}$ to ^{137}Cs in July 1974 was 0.094%. This figure is probably representative of the Irish Sea ratio at this time as it was shown not to vary between points within 10 km of the Windscale outfall and points 75–100 km from the

Table 2 Comparison of Minch nuclide inventories and ratios with fallout

	^{137}Cs	Inventories ^{90}Sr (mCi km ⁻²)	$^{239,240}\text{Pu}$	$^{137}\text{Cs}/^{90}\text{Sr}$	Ratios $^{238}\text{Pu}/^{239,240}\text{Pu}$
Water	—	93	—	6.2	0.14
Water plus sediment	630	—	3.3	—	—
Fallout	80	55	1.5	1.0	0.04

outfall. It differs significantly from the ratio, 0.043^{90}_{e} , observed in 1976 in the water column of the Minch. If the 1976 Minch water was the same water mass as characterised the Irish Sea in July 1974, one could conclude from the $^{239,240}\text{Pu}/^{137}\text{Cs}$ ratio change that only 46% of the soluble plutonium that was associated with the ^{137}Cs transported by the coastal current, survived the passage to the Minch. This conclusion, that rather less than half as much of the soluble plutonium avoids sediment uptake during transit from the Irish Sea to the Minch, implies that Windscale 'soluble' plutonium is only partly 'qualitatively similar' to ^{137}Cs . That the details of the separation of these two species may be of predictive importance is indicated by our preliminary data concerning sediments from the Flex area, of the North Sea, where ^{238}Pu to $^{239,240}\text{Pu}$ ratios, as do those of ^{134}Cs to ^{137}Cs , indicate significant delivery of Windscale radionuclides.

Fourth, from comparison of the ratio of ^{241}Am to $^{239,240}\text{Pu}$ observed in the Minch, against that reported in releases from Windscale¹⁸, some conclusions can be drawn about the relative mobilities of these two transuranium elements in marine coastal waters. Hetherington *et al.*¹⁸ have reported the mean ratio ^{241}Am to $^{238,239,240}\text{Pu}$ in Windscale releases to have been 2.56 in 1974, 1.66 in 1973 and 1.40 in 1972; it has also been reported¹⁹ that there were very wide fluctuations in this ratio, month to month, in 1974 releases. The mean ratio observed in the water of the Minch, 0.12, confirms that a very much greater proportion of ^{241}Am than of plutonium is immobilised during travel in the coastal current. A similar conclusion can be drawn from the low $^{241}\text{Am}/^{239,240}\text{Pu}$ ratios recently reported by Murray⁴ in seawater collected in 1975 from around the Orkney Islands. Although reports have consistently shown^{3,15} high ratios of ^{241}Am to plutonium in attached algae like *Porphyra*, it is likely that the major process immobilising ^{241}Am is association with sediments. This is indicated by the ratio of 0.33 observed in the surface sediments of the Minch, compared with the 0.12 observed in the overlying water. Some of the difference in the two ratios may be attributed to ingrowth of ^{241}Am from its parent ^{241}Pu (as discussed in refs 18, 20) but we believe most of the effect should be attributed to separation of americium and plutonium in the water column. We have described elsewhere²¹ differential behaviour of americium against plutonium from fallout in oceanic water columns. We submit that Hetherington *et al.*¹⁸ were unable to see this differential behaviour in the Irish Sea because of the fluctuations in supply ratio, and because trajectories were too short for the differences to be easily measurable.

Analyses of long-lived radionuclides in a water station and sediment core from the Minch have, therefore, confirmed the presence of Windscale-produced ^{90}Sr , ^{134}Cs , ^{137}Cs , ^{238}Pu , $^{239,240}\text{Pu}$ and ^{241}Am . Careful examination of the evidence for changes in the various ratios of these nuclides from those reported in the Windscale release stream has also (1) supported an improved estimate of the northward rate of movement of these nuclides in the coastal current; (2) confirmed that Windscale caesium behaves biogeochemically about as does that from fallout; (3) indicated that the soluble fraction of Windscale plutonium may qualitatively behave like ^{137}Cs , but that only some fraction of it survives travel to the Minch, relative to ^{137}Cs . The size of this fraction, put at about one-half from these measurements, and its possible variation in space and time should be determined; (4) demonstrated a large differential in the behaviour of ^{241}Am and $^{239,240}\text{Pu}$, in that americium seems to sediment out of the coastal current even sooner than does plutonium after introduction from Windscale.

This work has been supported by the US Energy Research and Development Administration. We thank our co-workers for help in sample collection and in radiochemistry.

Surge activity on the Barnes Ice Cap

THERE are conflicting opinions¹⁻⁵ on the occurrence of surges in the major ice sheets, deduced in many cases by indirect means. Where an ice sheet surges directly into the ocean, sea-level rise may be catastrophic. Surges in ice sheets may help to explain the apparent difficulties of accounting for the magnitudes of the decay rates deduced for the Laurentide Ice Sheet in terms of energy requirements for melting ice⁶. That is, large areas of that ice sheet became much thinner than was supposed, a suggestion made on the basis of marine core evidence¹. Pure computer simulations¹⁰ have shown that cyclic surging of the major ice sheets seems to be possible. This report shows that several surges have occurred within the last millennium on the Barnes Ice Cap, a small subpolar ice sheet on Baffin Island, Canada (Fig. 1).

This ice cap is a remnant of the North American Laurentide Ice Sheet¹¹. Surge scars on the ice cap have been tentatively identified¹² and one surge area was subsequently documented in some detail¹³. Now, five distinct surge scars of different ages have been identified with the help of Landsat imagery (Fig. 2). The scars all lie on the south-west side of the ice cap, which is thought to be significant because the south-west margin of the ice cap is, on average, 130 m lower in altitude than the north-east margin and because the orientation of the axis of the ice cap causes about 5% more direct solar radiation to be received on the south-west facing slopes¹⁴. Therefore, the average bulk temperature of the ice on the south-west side should be higher than that of the north-east side. The attainment of basal conditions favourable to surges should thus be expected first on the south-west side.

Except where immediately adjacent to proglacial lakes, the ice margin is frozen to the bed^{15,16}. Measurements (D. F. Classen, unpublished) indicate that ice at the pressure melting point exists at the base in the interior (Fig. 3) and approximate calculations¹³ indicate that this condition could be widespread. Horizontal velocity measurements (Fig. 3) tend to confirm this deduction since considerable basal sliding must be present.

Conn and Bieler Lakes are evidently formed as a result of the ice cap obstructing water flow along the natural slope of land. Generator and Blanchfield lakes have been formed by relatively recent surge ice which has interfered with previous drainage away from the ice cap. The presence of these lakes tends to accelerate ice flows at the margins¹⁵ compared with locations without lakes^{16,17}. Thus, part of surge areas numbers 1 and 3 may be suffering delayed 'recoveries' because of the proglacial lakes.

The general features of the surge scars are: (1) the presence of third and occasionally fourth order meltwater channels. These occur within the large surface depressions characterised by highly irregular topography not related to bedrock topography. The depressions displace the ice divide, and the corresponding bulged margins often extend well beyond the

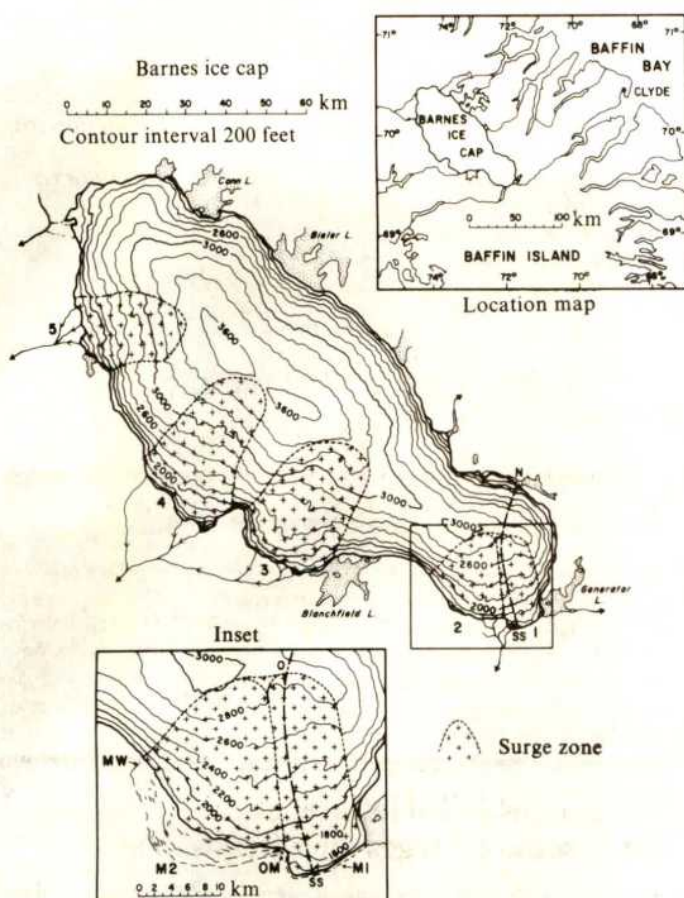

Fig. 1 Map of Barnes Ice Cap showing locations of former ice surges. Inset of south dome area shows location of transect along which data are presented in Fig. 3. Note moraine ridges (MW, M2, OM) associated with surge area no. 2. M1 marks recent moraine adjacent to surge area no. 1.

average line of the ice edge (Fig. 2). (2) Irregular foliation, defined by alternate dark- and light-banded ice (Fig. 2) is developed near the margins¹⁶ and indicates the presence of large shear strains. Measurements¹⁷ in non-surged areas show that the horizontal component of the ice flow vector is roughly parallel to the maximum principal strain rate direction (implying small shear strains) whereas within surge area no. 1, divergence between these quantities reaches 40° (G.H., unpublished). (3) Lakes occur on the ice surface due to trapping of meltwater in local depressions. While many of these lakes are visible on 1961 aerial photographs, some are visible on Landsat imagery

Fig. 2 Landsat image of Barnes Ice Cap (Channel 7, August 1974) showing surge scars. Surge areas 1 and 2 are partly obscured by cloud. Note evidence of intense shear strain in lower part of surge area no. 3 where ice is banded and the existence of lakes in surge area no. 5 (dark patches). The crown of the ice cap is covered by snow (white area) and meltwater streams cause the streak patterns.

(Fig. 2). Several moulines traversing cold ice are present at the margins. (4) Major streams, which flow west from the ice cap, can all be traced to the major surge areas (Fig. 1). (5) Moraines adjacent to the surge lobes tend to be well developed particularly when the surge is recent, since the moraines initially contain a substantial ice core. Also, recently overridden and pushed sediments may be seen near SS in Fig. 1. Ice depth soundings (J. W. Clough, unpublished and refs 18, 19) in surge zones 1,

Fig. 3 Cross section through south dome from north-east to south (see Fig. 1) showing ice thickness, temperature, surface flow rates and net mass balance. Note relative irregularity of measured quantities on south (surge) section compared with the same quantities on the north-east section. PP, present profile; PPP, postulated pre-surge profile. Isotherms are shown in short-dashed lines where values have been estimated and long-dashed lines where measurements have been obtained.

2 and 3 show that there, the surface profile does not owe its shape to the basal topography in terms of standard flow theory²⁰. These profiles cannot be fitted to established equilibrium ice-cap profiles²⁰ whereas the contiguous profiles on the north-east side can^{13,17}. Profile PP (Fig. 3) is taken through O-N and O-SS-flowlines (Fig. 1). Plotted isotherms are based on measured values and approximate computation¹⁰. As this is not a steady state situation, the correct solution can only be found by successfully modelling the complete surge or by total measurement. Nevertheless, at least some, and possibly a substantial part, of the base may be at the pressure melting point, switching to cold base at about 18 km down flowline O-SS. Profile PPP is an hypothetical pre-surge parabolic profile which would seem to satisfy mass conservation after allowing for long term mass balance¹⁰. Recent surface net ice balance is also plotted, and comparing this with vertical ice flow values (Fig. 3) it can be seen that, whereas the north-east side is approximately near equilibrium, the south-west side is rapidly wasting. Furthermore,

Fig. 4 Cross section through ice cap along two opposing flow lines. The south-west flow line is along the centreline of surge area no. 3. Coordinates and dimensions for equation developed in the text are shown. PP and PPP are as in Fig. 3.

the wavy character of the vertical ice flow on the south-west side indicates a disturbed dynamic flow regime.

This surge could have occurred as recently as 1927 or just before the turn of the century depending on the mass balance¹³, interpretation of the moraine ages²¹, and on the credibility of expedition accounts by Inuit from Clyde (Fig. 1).

Surge no. 2 is associated with a significant frontal moraine system (Fig. 1: inset, Fig. 2 and ref. 21) which may be interpreted in terms of cyclical surge activity with a period of 300–400 yr, spanning a period warmer than today and the 'Little Ice Age'. Morainial geometry indicates that local ice-cap dynamics was involved in their formation. The outer moraine curves sharply towards the ice cap at the north-west end (MW in Fig. 1: inset); at the eastern end (OM) it is truncated by the no. 1 surge lobe. The general retreat of the ice margin (M2) after about AD 500 (J. T. Andrews, personal communication) was punctuated by events at ~AD 900, ~AD 1200, ~AD 1500 and ~AD 1900 (or contemporaneously with surge no. 1)²¹.

Surge no. 3 may have reached a maximum position in about AD 1700 when it caused the formation of Blanchfield Lake in a more expanded form¹⁸. Area no. 4 has similar features to no. 3 and may be of comparable age whereas area no. 5 may be much older. The surface contains low intensity foliation and several large lakes. The inferred cyclic surging of diminishing extent seen for surge area no. 2 may or may not have been present in the other areas, but is a mechanism for maintaining a long-term surge scar.

Study of the surge mechanism is hindered by the lack of data that apply before and during the early stages of the surge. But it seems reasonable to assume that the mechanism described by Schytt²² applies. Figure 4 shows the profile through surge area no. 3 (PP). Let the parabolic pre-surge profile PPP be defined by ice thickness $H(x)$ and radius R of which only an outer portion $R-L$ is frozen to the bedrock. The length L ($< R$) is supposed to grow during a surge build-up. The amount of interior ice at the pressure melting point is thought to be controlled by heating of the upper surface as a result of superimposed ice build-up at the surface over sufficient period of time (10^3 – 10^4 yr). In this way, the onset of surging is related to climate.

As the water layer, represented by L , spreads, more interior ice is able to slide and because of its higher temperature, it will creep faster than the cold marginal ice. A predominantly mechanical mode of failure of the ice dam may follow when

$$\int_0^H \sigma_{xx} dz = \int_L^R \sigma_{xz}^b dx$$

where $\sigma_{xx}(z)$ is the horizontal component of the stress tensor at $x = L$ and $\sigma_{xz}^b(x)$ is the basal shear stress $L < x < R$. The

catastrophic flow which ensues might best be modelled using the finite element method incorporating joint elements (T. Q. Nguyen, unpublished).

A similar process may have occurred in the decaying phases of the Laurentide Ice Sheet in which surges have been inferred from the geological record⁸.

The rise and fall of intracellular pH of sea urchin eggs after fertilisation

JOHNSON *et al.*¹ have reported an increase in the intracellular pH of sea urchin eggs, seen between 1 and 4 min after insemination, that results from the efflux of H^+ ions from the cells. The rise in pH can be induced by artificial activators of metabolism such as ammonia, or organic amines such as procaine. They have postulated that this increase in cellular pH is responsible for the metabolic derepression of the eggs and the initiation of embryonic development^{1,2}. Our interest in the control of the initiation of DNA synthesis in these synchronously dividing cells³, coupled with their method¹ for estimating the intracellular pH, led us to attempt to determine if fluctuations in pH occur during the cell cycle. Here we confirm the important observation of a rise in pH at fertilisation, and we report that the rise is soon followed by a gradual drop in pH to final values lower than those of the unfertilised condition.

The pH of homogenates of unfertilised sea urchin eggs averaged 6.34 ± 0.1 (41 determinations). By 10 min after insemination the pH rises to an average of 6.76 ± 0.16 (five determinations, Fig. 1). These values are in close agreement with those of 6.48 (unfertilised) and 6.76 (10 min after insemination) reported by Johnson *et al.*¹ with the exception that their average difference between unfertilised and fertilised of 0.28 is smaller than ours of 0.43 units. After a peak rise at 10 min after insemination (Fig. 1), the pH steadily decreases, reaching the value of the unfertilised eggs (6.46) by 70 min and attaining a final value of 6.18 by 140 min, a value that is maintained to at least the 48 h, mid-gastrula stage. No correlation of pH with stage of the cell cycle was found. Identical results were obtained when unfertilised eggs were parthenogenetically activated with the Ca^{2+} ionophore A23187 (ref. 4). It can therefore be concluded that although the initial rise in pH may be obligatory to metabolic activation, maintenance of elevated intracellular pH is not necessary to sustain embryonic development.

Does measurement of the pH of egg homogenates give a valid estimate of intracellular pH? The possibility that

Fig. 1 The pH of sea urchin egg homogenates plotted against time after insemination (average of five separate experiments). Eggs of *Strongylocentrotus purpuratus* were stirred in seawater (pH 7.8) at 1% (v/v) concentration in a 15 °C room in which all media were stored and all pH determinations were accomplished. Aliquots of 50 ml of the culture were sedimented in a 50-ml conical centrifuge tube by hand centrifugation. The seawater was removed and the eggs suspended in 30 ml of bicarbonate-free artificial seawater, pH 7.8 (ref. 1). After resedimentation and removal of the artificial seawater the eggs were resuspended in 5 ml of 0.55 M KCl adjusted to pH 7.0 with HCl and NaOH. The suspension was transferred to a 20-ml Dounce homogeniser and 10 passes were made by hand with a tightly fitting Teflon pestle. Microscopic examination showed that no intact eggs or egg fragments remained. The pH was measured immediately with an expanded scale Corning Model 10 pH meter equipped with a Thomas 4094-L15 universal combination electrode. The timing of the first two periods of DNA synthesis³ is denoted by S on the horizontal axis. The protein concentration of the homogenate was 11.6 mg ml⁻¹. Homogenates containing one half or twice as much protein did not show significant pH differences.

the rise and fall in pH might not be a true estimate of intracellular pH but merely a reflection of compartmentation of H⁺ or OH⁻ ions in organelles such as mitochondria, was investigated by destroying all membrane-enclosed compartments by homogenisation in 0.5% Triton X-100. The results of this experiment (Table 1) show that the rise and fall in pH was also obtained in Triton, suggesting the method might prove to be valid for estimating total cellular pH of these and of other types of cells.

Fertilisation results in an irreversible activation of synchronous cycles of DNA synthesis and cell division³. We previously showed that DNA synthesis in unfertilised sea urchin eggs can be reversibly initiated by treatment with the local anaesthetic procaine hydrochloride⁵. If procaine is removed when the cells are in mid S phase, DNA synthesis abruptly halts. Other workers have shown that procaine treatment causes the efflux of H⁺ ions from these cells which results in a rise in intracellular pH; that is, the weakly basic nature of procaine is not responsible for the observed rise in cellular pH^{1,6}. We wondered if the removal of procaine from eggs would result in a

decrease in intracellular pH which might serve, somehow, as a switch to turn off DNA synthesis. We repeated our earlier experiments of treating unfertilised eggs with 10 mM procaine in seawater for 75 min, then washing out the drug, reculturing in fresh seawater, and determining the pH of egg homogenates. On addition of procaine the intracellular pH rises sharply and remains high for the duration of procaine treatment (Fig. 2). When procaine was washed out and the eggs returned to normal seawater, the intracellular pH rapidly dropped to the value of the untreated eggs, pH 6.46 (Fig. 2).

After their peak rise at 10 min after insemination, fertilised eggs (Fig. 1) required 60 min to return to their unfertilised pH. After procaine removal, however, unfertilised eggs required only 20 min to drop to their original pH (Fig. 2). This difference in rate of pH drop suggests that different mechanisms may underlie the fall in pH fertilised eggs and in unfertilised eggs recovering from procaine treatment. Support for this hypothesis was found in experiments in which fertilised eggs and procaine-activated eggs were treated with the metabolic poison dinitrophenol (DNP). For example, eggs were pretreated with DNP 30 min before fertilisation or procaine addition. Because DNP kills sperm, the eggs to be fertilised were washed from DNP into seawater (5 min washing time) and sperm immediately added. DNP was then added again 2 min after insemination. The normal rise in pH occurred, peaking at 10 min (Fig. 3), but the greater part of the subsequent drop in pH did not occur, and the cells maintained a pH of 6.65 for the duration of the experiment. Identical results were obtained when eggs were parthenogenetically activated by the ionophore A23187 in the continued presence of DNP. In response to procaine, the pH of DNP-treated, unfertilised eggs rose to 6.90 and remained at that value until 75 min when the procaine was washed out with seawater containing DNP. The result was an almost immediate drop in pH back to the original value (Fig. 3). The rise in intracellular

Fig. 2 Intracellular pH and the addition and removal of procaine. Procaine hydrochloride (10 mM, Sigma) was added to a suspension of unfertilised eggs and a rapid rise in the intracellular pH immediately occurred which was sustained for the duration of procaine treatment. At 75 min the procaine was removed (arrow) and the eggs returned to normal seawater⁵. There was a rapid fall in intracellular pH to the untreated value. To be certain that residual procaine was not influencing the pH of homogenates we added 0.5 ml 10 mM procaine to homogenates and found that it did not change the observed pH.

Table 1 The pH of egg homogenates in 0.55 M KCl containing 0.5% Triton X-100

Time after insemination (min)	pH
0	6.39
10	6.70
60	6.58
120	6.43

pH between 0 and 10 min after insemination or after procaine addition in the presence of DNP is evidence that H^+ ion release from mitochondria is probably not responsible for excretion of H^+ from the cells. The subsequent fall in pH in fertilised eggs may depend on the synthesis of ATP (with the reservation that metabolic inhibitors can have nonspecific effects). The drop in pH of the unfertilised eggs immediately after procaine removal in the presence of DNP shows that in these eggs the drop is independent of the production of metabolic energy.

The normal drop in intracellular pH of fertilised eggs (Fig. 1) is the most protracted metabolic change yet reported in the metabolic activation of development², a final value not being reached until 140 min after insemination. This is well after the completion of the first mitosis and the second S phase³. The period of the pH drop corresponds to the period of the activation of the transport systems for amino acids^{7,8} and nucleosides^{8,9} and the increase in the rate of protein synthesis⁷ in these cells. It is tempting to speculate that the development of transport capabilities might be linked to the lowering of intracellular pH. In this context, we have reported that the transport of thymidine into unfertilised eggs treated with procaine is only 2% that of fertilised eggs, whereas DNA synthesis in procaine occurs at roughly 50% the rate of fertilised eggs⁹. The high intracellular pH maintained in procaine may somehow inhibit the development of the transport systems in the cell membranes.

DNA synthesis is reversibly activated by the addition and removal of procaine⁵. The rapid drop in pH after procaine removal and the insensitivity of the drop to respiratory poisons such as DNP show that procaine may activate DNA synthesis by a different mechanism than does fertilisation. Amphipathic drugs such as procaine are thought to affect cells by intercalating into the lipid bilayers of the cell membrane. This can cause the expansion of the membrane which may result in a change in its permeability characteristics¹⁰. Procaine may open channels for H^+ ion excretion which would result in an elevation

of the intracellular pH. After removal of procaine from the external medium, procaine loss from the membrane may re-establish normal permeability, thus allowing the cells to return to a lower pH. The rise and fall in pH on the addition and removal of procaine correlates well with the turning on and turning off of DNA synthesis⁵ indicating that, in these conditions of artificial activation, the control of DNA synthesis may indeed be linked to changes in intracellular pH.

We thank David W. Deamer and Robert J. Gillies for helpful discussions. This work was supported by the USNIH.

Note added in proof: Nishioka and Epel using the homogenisation method, and Shen and Steinhardt using pH microelectrodes have confirmed the transient rise in pH of sea urchin eggs after fertilisation. The pH values obtained by both these groups are slightly higher than those we report here.

Calcium uptake during mitosis in the myxomycete *Physarum polycephalum*

THE notion that Ca^{2+} is involved in the regulation of the kinetic and contractile events associated with mitosis in eukaryotic cells is attractive. The contractile proteins, actin and myosin, have been identified in nuclei of *Physarum polycephalum*¹ and their interaction is apparently regulated by Ca^{2+} (ref. 2). The formation of spindle microtubules may also be sensitive to Ca^{2+} (ref. 3), although as yet there is little evidence of Ca^{2+} fluctuations during mitosis. Macropasmodia of the myxomycete *P. polycephalum* are particularly suited to the analysis of events during the cell cycle and mitosis. Synchronous mitoses of large numbers of nuclei proceed against a lowered background of contractile events in the surrounding cytoplasm as cytokinesis does not occur and cyclosis or cytoplasmic streaming slows or ceases during the mitotic period⁴. Extranuclear filaments form in telophase⁵, presumably to participate in nuclear division, but earlier nuclear mitotic events should be amplified. We present evidence here that cyclic uptake and release of Ca^{2+} from the extracellular medium occurs during mitosis in *P. polycephalum*, and that these fluctuations correlate with specific structural and kinetic events in the mitotic nuclei.

Plasmodial Ca^{2+} uptake was monitored by adding $^{45}Ca^{2+}$ to the medium, removing samples of plasmodia at 1-min intervals and assaying the radioactivity accumulated. During the interphase period before mitosis, a rapid and regular cyclic uptake and release of $^{45}Ca^{2+}$ is seen (Fig. 1). The frequency of this process is similar to oscillations in light absorption measured in a small plasmodial segment (Fig. 1 inset) which Sachsenmaier *et al.*⁴ correlated with shuttle streaming. Similar observations on cyclical variation in free cytoplasmic Ca^{2+} concentrations during shuttle streaming in *Physarum* have been made by Ridgway and Durham¹⁰. During mitosis a different pattern of Ca^{2+} uptake is observed (Fig. 1). Although some fluctuations in uptake still occur, the regular periodicity detected in interphase is not apparent. In metaphase there is an outflow of more than half of the $^{45}Ca^{2+}$ accumulated during prophase and uptake is substantially reduced for 3-4 min. During

Fig. 3 Effect of dinitrophenol on the fall in pH of fertilised eggs and procaine-activated eggs. Unfertilised eggs were treated for 30 min with 2.5×10^{-3} M DNP in seawater. Eggs to be fertilised were quickly washed from DNP into seawater (the wash required 5 min), sperm was added and 2 min later DNP was reintroduced. The normal rise in pH occurred but the subsequent drop in pH was blocked. Procaine was added directly to the DNP-treated unfertilised eggs and the elevation of pH immediately occurred. At 75 min the procaine was washed out with seawater containing DNP. The intracellular pH rapidly dropped to the value close to that of untreated eggs. ●, Fertilised eggs; △, procaine-treated unfertilised eggs.

Fig. 1 Time course of $^{45}\text{Ca}^{2+}$ uptake during interphase and mitosis. Macroplasmodia were initiated and cultivated⁶ on filter paper disks at 25 °C using a semi-defined medium⁷ (EDTA, thiamine and biotin were omitted, CaCl_2 was increased to 5.2 mM, and 0.15% yeast extract was included). Transition through the cell cycle was monitored by smearing small fragments in 50% glycerol-ethanol and examining by phase contrast microscopy. $^{45}\text{Ca}^{2+}$ (final concentration $2\ \mu\text{Ci ml}^{-1}$) was added (at 'zero' time) to the growth medium of a macroplasmodium either during interphase before the third mitosis (a) or shortly before it entered the third mitosis (b). $^{45}\text{Ca}^{2+}$ uptake was measured by excising small pieces of plasmodium at intervals after $^{45}\text{Ca}^{2+}$ addition, washing twice by immersion for 10 s in medium containing a 10-fold excess of unlabelled Ca^{2+} , then rinsing briefly in distilled water to remove traces of the medium. The plasmodium was scraped from the filter paper and homogenised in 1 ml of distilled water. Aliquots were taken for liquid scintillation counting and protein assay⁸. The scales are different for the ordinate of the two traces as ^{45}Ca accumulation fluctuates more intensively during interphase. P designates prophase; M, metaphase; and A anaphase as observed by microscopy⁹. The inset shows a tracing of the pattern of A_{380} changes observed in a Varian 635 spectrophotometer when light is directed through a small region of plasmodium growing on an agar-coated piece of Perspex, following the method of Sachsenmaier *et al.*¹. The maximum absorbance change in peaks represents 0.05 units.

anaphase, a large overall accumulation of $^{45}\text{Ca}^{2+}$ once again takes place.

The correlation between Ca^{2+} uptake and mitotic phases is clearer when 5-min pulses with ^{45}Ca are monitored. The results of three such experiments are shown in Fig. 2 and similar patterns were obtained in seven other experiments. Such reproducible cycles in Ca^{2+} uptake were not as evident when the pulse time was shortened to 3 or lengthened to 7.5 min. Peaks in Ca^{2+} uptake are found to coincide with prophase and anaphase while uptake is low during metaphase. The time course of Ca^{2+} uptake during metaphase (Fig. 2 inset) indicates that in the 5-min pulse period, $^{45}\text{Ca}^{2+}$ is initially taken up but is then released back into the medium; in prophase and anaphase, by contrast, uptake is continuous and approximately linear with time. Uptake of Ca^{2+} during interphase is more irregular as the initial 5-min period in Fig. 1 indicates.

The large amplitude cycles of $^{45}\text{Ca}^{2+}$ uptake are not reflected in fluctuations in the total amount of Ca^{2+} present in the plasmodia. Samples taken during mitosis gave a range of values from 233 to 254 nmol Ca^{2+} per mg protein when measured by atomic absorption spectroscopy, showing no correlation with the pulse experiments. These results show that the cyclical uptake of Ca^{2+} during mitosis may be into particular pool(s)

within the plasmodium, rather than being due to generalised uptake and release of a large fraction of cellular Ca^{2+} and that this pool is not in equilibrium with the major pool of Ca^{2+} present in the plasmodium. Although mitochondria¹¹, cytoplasmic vesicles¹², and endoplasmic reticulum¹³ have been identified as sites for Ca^{2+} sequestration in *Physarum*, we have not so far been able to identify a specific 'mitotic' pool of Ca^{2+} in nuclei, mitochondria or other particulate fractions of the protoplasm.

We have found that Ca^{2+} influx in microplasmodia is largely energy dependent, while efflux is stimulated by KCN. A similar response is observed in the yeast *Schizosaccharomyces pombe*¹⁴. To determine whether the fluctuations observed in Ca^{2+} uptake during mitosis are related to variations in respiratory energy supply, oxygen uptake rates during mitosis were examined. The pattern observed (Fig. 3) is almost identical to that for Ca^{2+} uptake. If the 5-min pulse period for Ca^{2+} uptake is taken into account, the coincidence of the curves could indicate that the changes in O_2 uptake precede those in Ca^{2+} uptake. Whether this relationship is a direct consequence of mitochondrial Ca^{2+} uptake or is related to respiratory energy production is not certain although the effect of caffeine on the motility of plasmodial fragments¹⁵ suggests that a caffeine-sensitive reticulum system is involved in protoplasmic motility. Energy-dependent uptake of Ca^{2+} could involve an active transport system in the plasma membrane, energy-linked endocytosis, or Ca^{2+} sequestration by intracellular organelles, all of which may depend on respiratory energy.

How might the movement of Ca^{2+} into and out of *Physarum* plasmodia be related to the events of mitosis? In heart and smooth muscle cells, an influx of external Ca^{2+} is believed to trigger a release of Ca^{2+} from intracellular stores¹⁶. In sea-urchin eggs, a vesicular system associated with the mitotic apparatus may regulate the local concentration of Ca^{2+} ions¹⁷. It is thus possible that the prophase and anaphase peaks of Ca^{2+} uptake we observe trigger Ca^{2+} release in or near nuclei, thus initiating or in some other way regulating chromosomal movement. During metaphase, when microtubules proliferate and chromosomal movements temporarily cease, a lower rate of influx of

Fig. 2 Uptake of $^{45}\text{Ca}^{2+}$ during mitosis in *P. polycephalum*. During the third synchronous mitosis (24–26 h after initiation), sectors of plasmodium on filter paper (approximately $1 \times 2\text{ cm}$) were removed and placed on a 200- μl drop of medium containing $^{45}\text{Ca}^{2+}$ ($2\ \mu\text{Ci ml}^{-1}$) at the times indicated. After incubation for 5 min at 25 °C the sector was treated as described in Fig. 1 and assayed for radioactivity and protein. a, $^{45}\text{Ca}^{2+}$ uptake observed in three separate experiments (■, ●, ○) during mitosis. b, Time course of $^{45}\text{Ca}^{2+}$ uptake over the 5-min pulse period during prophase (●), metaphase (○), and anaphase (■). Uptake over 5 min during interphase is shown in Fig. 1a. The time course of uptake was reproducible for each phase of the mitotic cycle in three experiments, although data is given here for a single experiment. The zero points for calcium uptake in (b) represent the times when the segments were placed on labelled medium.

Fig. 3 Comparison of oxygen and $^{45}\text{Ca}^{2+}$ uptake during mitosis. Segments of plasmodium (approximately 1 cm^2) were excised from a macroplasmidium during mitosis and the plasmodial segment was removed from its filter paper support by immersing in growth medium and gently prising it free. Oxygen uptake (\circ) was measured in a Gilson oxygraph with a Clark-type oxygen electrode by placing the plasmodial piece in 3 ml of respiration buffer containing 350 mM mannitol and 10 mM MES buffer at pH 6.0. Each point represents the initial O_2 uptake rate at the time when the segment was placed in the oxygen electrode. Rates were usually linear for at least 1 min. Ca^{2+} uptake (\bullet) was measured in the same plasmodium 1 min later using the 5-min pulse method described in Fig. 2.

Ca^{2+} may be necessary to reduce local Ca^{2+} concentrations so that tubulin polymerisation is promoted³.

Killed *Listeria monocytogenes* vaccine becomes protective on addition of polyanions

In the interaction between macrophages and intracellular parasites, microbial components which prevent phagosome-lysosome fusion^{1,2} have a decisive role. The resistance to facultative intracellular parasite *Listeria monocytogenes* is a form of cell-mediated immunity³, as it can be passively transferred with viable lymphoid cells⁴. Resistance to *listeria* infection can be induced by sublethal numbers of

Table 1 Resistance to infection following treatment with DS 500 and immunisation with dead *listeria*

No. of bacteria	DS 500 dose (mg per kg body weight)				
	50	25	12.5	5	None
10^9	3/4*	6/6	5/6	4/6	0/6
10^8	6/6	6/6	0/6	0/6	0/6
10^7	0/6	0/6	0/6	0/6	0/6
None (saline)	0/6	0/6	0/6	0/6	0/6

Groups of BALB/c mice were injected i.p. with DS 500 or saline 1 d before i.p. injection of heat-killed (56°C for 60 min) *listeria* or saline. Seven days later all animals were challenged i.p. with 50 LD_{50} *listeria*. The numbers of survivors on the numbers of mice challenged were recorded 2 weeks after challenge.

*In this group two mice died after immunisation.

viable *listeria*^{5,6}. Induction of resistance by non-viable *listeria*, however, is effective only after repeated injections of *listeria* preparations in combination with lipopolysaccharides⁷. Lipopolysaccharide is cytotoxic against macrophages^{8,9}, suggesting that the difference in processing of viable and dead microorganisms by macrophages might explain the induction of resistance by vaccine of live and not of dead bacteria. Impairing macrophage activity might result in a processing of dead *listeria* advantageous for the induction of resistance. We show here that killed *L. monocytogenes* vaccine becomes protective when the polyanions dextran sulphate (DS 500, molecular weight 500,000, Serva) and suramin (Bayer) are added. These polyanions are known to inhibit phagosome-lysosome fusion in macrophages^{2,10}. Moreover, dextran sulphate is a potent adjuvant for both humoral¹¹ and cell-mediated responses¹². The latter might be particularly important in view of the requirement of cell-mediated immunity for resistance to *listeria*³.

BALB/c mice were injected intraperitoneally (i.p.) with graded doses of DS 500 or suramin and 1 d later with different numbers of heat-killed *listeria*. The challenge injection of $50 \times \text{LD}_{50}$ (dose causing 50% killing) was given i.p. 7 d later. Pretreatment with DS 500 allowed induction of resistance with 10^9 and 10^8 dead *listeria* (Table 1). With the latter numbers of bacteria protection could only be induced following high doses of DS 500. The dose of 50 mg DS 500 per kg body weight probably damaged the phagocytic system to such a degree that 10^9 *listeria* were badly tolerated as an immunising dose.

Doses of DS 500 over 50 mg per kg in combination with 10^7 *listeria* did not result in protection. The protection afforded by suramin treatment was slightly less (Table 2). Complete protection was only found in the combination of highest doses suramin and *listeria*. But again one animal did not survive the immunisation.

The doses of suramin required to give protection in addition to injections of dead *listeria* are about 10 times as high

Table 2 Resistance to infection after treatment with suramin and immunisation with dead *listeria*

No. of bacteria	Suramin dose (mg per kg body weight)					
	500	300	150	50	15	None
10^9	5/5*	5/6	5/6	4/5	4/5	0/3
10^8	4/6	2/6	1/6	0/4	0/4	0/3
10^7	0/6	0/6	0/6	ND	ND	ND
None (saline)	0/6	0/6	0/6	0/6	0/3	0/3

Experimental details as for Table 1. ND, Not done.

*In this group one mouse died after immunisation.

as those of DS 500. A similar ratio of activities was found for *in vitro* inhibition of phagosome-lysosome fusion where the optimal inhibiting doses of suramin and DS 500 were respectively 200 and 30 µg (M. J. de Reuver, personal communication). The influence of the interval between DS 500 and immunising injection was studied using 30 mg DS 500 per kg (Table 3). With an interval of 8 h between DS 500 and 10⁹ listeria all mice died after immunisation (data not shown). Reduction of the dose of DS 500 to 15 mg per kg, followed by 10⁹ bacteria resulted in complete protection (Table 3). This suggests that the interval between injections of the toxic products DS 500 and dead listeria should not be too small if high doses of both are used.

Host immunity and survival of intracellular parasites depend on a delicate balance of host-parasite interplay. The ingestion of previously killed intracellular parasites by macrophages leads to rapid and extensive phagosome-lysosome fusion¹³, but no resistance to infection. Resistance to intracellular growing bacteria can in general only be achieved by immunisation with viable bacteria. Impairing macrophage function by DS 500 resulted in increased susceptibility to infection with listeria^{14,15}. These results suggest that although macrophages are host cells for listeria,

Table 3 Effect on resistance to infection of the interval between DS 500 treatment and immunisation with dead listeria

No. of bacteria	DS 500 treatment on				No treatment
	Day -2	Day -1	-8 h	Day -1	
10 ⁹	5/5*	6/6	6/6	5/5*	0/6
10 ⁸	3/6†	6/6	2/6	0/6	0/6
None (saline)	0/6	0/6	0/6	0/6	0/6

Groups of BALB/c mice were injected i.p. with 30 mg DS 500 per kg before or after injection of dead listeria or saline (controls). The groups receiving injections with the 8 h interval were treated with 15 mg DS 500 per kg. Other details as for Table 1.

*In these groups one mouse died after immunisation.

†One mouse died within the 2 weeks recording period after the challenge, but two mice died 1 week later.

the degree of processing of the listeria is decisive for the induction of resistance. The probably incomplete processing of viable listeria by macrophages seems to be a prerequisite for the induction of resistance. The more complete digestion of non-viable listeria does not result in protection.

The finding that lower numbers of non-viable bacteria (10⁸) needed high doses of polyanions to obtain protection supports the hypothesis that the degree of digestion of bacteria should be limited in order to induce resistance. Experiments are in progress to isolate the fraction(s) of listeria responsible for the induction of resistance.

Non-infectious virus induces cytotoxic T lymphocytes and binds to target cells to permit their lysis

MUCH current interest is focused on the involvement of expressed products of the major histocompatibility (*H-2*) gene complex, especially those associated with the K and D regions of *H-2*, in inducing cell-mediated immune responses and in permitting recognition and killing by cytotoxic thymus-derived lymphocytes (CTL). Observations in many laboratories have led to the generalisation that syngeny between stimulator and target cells at the K and/or D region of *H-2* is required for CTL activity to virus-infected cells¹⁻³, minor histocompatibility antigens⁴, the male H-Y antigen⁵ and chemically modified syngeneic cells⁶⁻⁹. This study asks three questions related to the genetic restriction of induction and expression of CTL: (1) can non-infectious virus efficiently induce CTL, (2) can non-infectious virus absorbed to target cells render them susceptible to killing by CTL, and (3) can non-infectious virus absorbed onto or chemically linked to cells induce CTL and does using allogeneic or xenogeneic carrier cells affect this induction?

Two major models have been proposed to explain the involvement of *H-2* antigens and foreign antigens, such as viral antigens, in recognition of target cells by CTL. The 'dual recognition' model proposes recognition of *H-2* and foreign antigens on the target cell surface by two separate receptors on the CTL while the 'adaptor-antigen complex' or 'modified self' model postulates a physical association between *H-2* antigens and the foreign antigen on the cell surface to form hybrid antigens containing elements of self and non-self^{2,10,11}.

Using 6/94 virus, a para-influenza type 1 virus antigenically related to Sendai virus, it has been shown that although only virus-infected cells histocompatible with the effector T cells can serve as susceptible target cells, syngeneic, allogeneic, and even xenogeneic virus-infected cells are capable of inducing virus-specific cytotoxicity¹². But, as the virus used in the previous study retained some infectivity, it was possible that the allogeneic and xenogeneic virus-infected cells used to induce CTL released

Table 1 Characterisation of anti-6/94 effector cells

Treatment	Live 6/94	BPL 6/94
Hold on ice	58	39
4 h at 37 °C	32	31
Nylon column nonadherent	58	48
Guinea pig serum (C)	54	39
Anti-Thy 1.2 + C	4	6
Rabbit α mouse Ig + C	ND	70
Rabbit α 6/94 + C	ND	34

BALB/c mice were injected i.p. with 100 µg of live or BPL-treated 6/94 virus. On day 5, spleen cell suspensions were prepared, treated as indicated and assayed against P815Y target cells incubated for 90 min with BPL-treated 6/94 virus immediately before labelling with Na₂⁵¹CrO₄. Cytotoxicity values are % specific lysis for an 18-h assay and spleen cell: target cell ratio of 50:1. Spontaneous release was 47%. Treatment with anti-Thy 1.2 serum removed 38% of the cells. ND, Not determined.

Fig. 1 Induction of anti-viral cytotoxic thymic-derived lymphocytes (CTL) by infectious and non-infectious 6/94 virus with assay on target cells pre-incubated with different amounts of non-infectious 6/94 virus. BALB/c ($H-2^d$) mice were injected i.p. with 100 μg of live 6/94 virus in phosphate buffered saline (Δ), with 100 μg of non-infectious 6/94 virus treated with BPL¹⁸ and verified negative for infectivity by serial egg passage and incubation with susceptible cells in culture (\blacksquare), or uninjected (\bullet). On day 5 spleens were removed and assays were performed for 18 h against P815Y ($H-2^d$) cells incubated with 0, 1, 5, 25 or 100 μg BPL-treated 6/94 virus (5×10^6 cells in 2 ml, 37°C , 90 min, washed and then labelled with ^{51}Cr chromate). All assays were carried out using lymphocyte-target cell ratios of 200:1, 67:1, and 22:1. Only data for 67:1 are shown for simplicity. *a*, Shows spontaneous release in 18 h as a % of total incorporation. *b*, Cytotoxicity in terms of % specific lysis.

virus which then infected host cells; the measured cytotoxicity might then have been induced by virus-infected (syngeneic) host cells.

To compare the immunogenicity of live and non-infectious 6/94 virus, BALB/c mice ($H-2^d$) were injected intraperitoneally (i.p.) with 100 μg of either infectious or β -propiolactone (BPL) inactivated¹⁷ 6/94 virus. Lymphocytes from these mice and uninjected controls were then assayed on day 5 against P815Y cells ($H-2^d$) incubated with 0, 1, 5, 25 or 100 μg of BPL inactivated 6/94 virus for 90 min before labelling with radioactive chromate. Figure 1*b* demonstrates that live and non-infectious 6/94 virus induced the same amount of cytotoxicity and that P815Y cells were made susceptible to killing when incubated with as little as 1 μg of non-infectious virus just before labelling. The rate of spontaneous release is increased as more virus is absorbed to the target cells (Fig. 1*a*), indicating that optimum assay conditions are a compromise between more virus per cell and increasing spontaneous release.

The cytotoxicity induced by both live and non-infectious 6/94 virus was shown to be mediated by CTL (Table 1). The cytotoxicity induced by both live and non-infectious 6/94 virus was not labile at 37°C as is true for 'natural'

killer cells^{13,14}. The activity was largely abolished by anti-Thy 1.2 serum and complement and was not diminished by removal of cells adherent to nylon wool or of cells killed by anti-mouse immunoglobulin and complement; it seems therefore that lysis is mediated by a T cell and not by a B cell or macrophage.

Non-infectious 6/94 virus was absorbed on to (1) P815Y cells which are $H-2^d$ like BALB/c; (2) EL4 cells which are $H-2^b$ and allogeneic to BALB/c, and (3) bovine kidney cells (MDBK) which are xenogeneic to BALB/c; all cells were washed extensively to remove any free virus, and injected i.p. into BALB/c mice.

Table 2 shows that 6/94 virus absorbed to all three cell types induced cytotoxicity against P815Y cells sensitised with either infectious or BPL-treated 6/94 virus. The 6/94 virus, like the well characterised Sendai virus, adsorbs rapidly to the cell surface, fusing its envelope with the cell membrane as a normal event in penetration¹⁵; once this occurs, therefore, virus would not be expected to desorb from the cells used for the injection of mice. To make it even less likely that the effective immunogen is free virus or virus that desorbed from the injected cells and reabsorbed to host cells, the xenogeneic MDBK cell and 6/94 virus were covalently linked using four additions at 10 min intervals of freshly diluted *bis*-diazotized benzidine (BDB) solution¹⁶. The results in Table 2 show that 6/94 virus covalently linked to xenogeneic cells is still able to induce cytotoxicity against 6/94 determinants on P815Y cells.

As was shown in work with CTL induced with 6/94 virus¹², we did not observe significant cell-mediated cytotoxicity of allogeneic EL4 cells or xenogeneic bovine kidney cells adsorbed with 6/94 virus. But, the lack of cytotoxicity by CTL on allogeneic and xenogeneic targets was not due to lack of expression of viral determinants or to an inability of the cells to be lysed, because all these cells were lysed by rabbit anti-6/94 virus antiserum and guinea pig complement (Table 3). This was also true for MDBK cells to which virus had been bound covalently. The P815Y and EL4 cells did not survive the BDB coupling conditions and hence were not tested.

In summary, our results show that non-infectious virus is immunogenic both as free virus and when fused with cells of the same or different $H-2$ as the host. Non-infectious virus covalently linked to xenogeneic cells also was immunogenic. These results make less likely, but *in vivo* experiments can never completely exclude, the possibility that macrophages process free or cell-bound virus and present viral determinants on a host $H-2$ background. Immunogenic determinants in these experiments are contained in the 6/94 virus and do not involve a complex with structures present on the cell carrying the virus. This finding and

Table 2 Induction of CTL with non-infectious 6/94 virus passively adsorbed to or covalently linked with *bis*-diazobenzidine to various cells

Immunising cells	Target cells		
	P815Y	P815Y (BPL 6/94)	P815Y (live 6/94)
None	1	6	9
P815Y (BPL 6/94)	8	39	47
EL4 (BPL 6/94)	5	35	26
MDBK (BPL 6/94)	—7	75	55
MDBK (BDB coupled BPL 6/94)	6	55	51

BALB/c mice were immunised with the indicated cells and assayed on day 5 for 18 h at 150:1 spleen cells: target cell against P815Y incubated with live or BPL-treated 6/94 virus or left without virus. Values are % specific lysis for the mean of triplicate determinations. Standard error of the mean was always less than 2 percentage points or 10% of the mean. Spontaneous release was 31% for P815Y, 54% for P815Y (BPL 6/94) and 48% for P815Y (live 6/94).

Table 3 Lysis of various target cells with anti-6/94 antibody and complement

	Uninfected	+ Live 6/94	+ BPL 6/94	Coupled BPL 6/94
P815Y	25	52	70	—
EL4	2	69	75	—
MDBK	2	42	34	47

For each target, 2×10^4 ^{51}Cr labelled cells in 50 μl were mixed with 50 μl 1:4 or 1:20 dilutions of rabbit anti-6/94 antibody, 50 μl of a 1:9 dilution of guinea pig complement was added. The mixture was incubated for 1 h at 37 °C, and one half the supernatant was counted. Values are % specific lysis for 1:20 initial dilutions of antiserum. Spontaneous release ranged from 3% to 24% for the ten different targets.

the restriction of lysis by CTL of histocompatible target cells displaying virus argues for a view of CTL possessing separate receptors for H-2 and for virus determinants. Thus, while it seems that both receptors must be bound for CTL activity to be expressed, CTL activity is apparently induced by viral determinants alone without involvement of histocompatibility antigens.

Effects of a nonapeptide FTS on lymphocyte differentiations *in vitro*

BACH *et al.*^{1,2} have reported the amino acid sequence of a putative thymic hormone isolated from pig serum³, a nonapeptide called FTS (*facteur thymique serique*). Natural and synthetic FTS showed high activity in the rosette test used as a bioassay^{1,2}. Bioassays for thymic hormones⁴, however, can be spuriously triggered by many substances of non-thymic origin⁵, a finding probably related to mediation by a cyclic AMP second signal⁶. Early steps in B-cell differentiation are also mediated by cyclic AMP (refs 6–9) and comparison of induction of T cells and B cells from committed precursor cells *in vitro* (the dual induction assay) enables a distinction to be made between selective and non-selective inducing agents^{7,8}. This is exemplified by induction studies in the mouse with

thymopoietin^{10,11} and ubiquitin^{7,12,13}. Bovine thymopoietin selectively induces T-cell differentiation and actually inhibits B-cell differentiation⁹. By contrast, ubiquitin is non-selective, inducing both T- and B-cell differentiation⁷. Ubiquitin at high concentrations does not induce differentiation whereas these high concentrations do not impair induction by thymopoietin or other agents^{8,14}. Another feature of induction by ubiquitin is its inhibition by the β -adrenoceptor-blocking drug propranolol, which is without effect on induction by thymopoietin⁷. We have evaluated synthetic FTS in the dual induction system in the chicken to determine whether it showed inductive selectivity appropriate to a thymic hormone, and have found that it induced non-selective differentiation of both T cells and B cells and closely resembled ubiquitin in its activity.

The nonapeptide, $\text{NH}_2\text{-Gln-Ala-Lys-Ser-Gln-Gly-Gly-Ser-Asn-COOH}$, was synthesised using solid-phase methodology (Peninsula, San Carlos, California). The purified peptide showed a single spot in four thin-layer chromatography systems and on high voltage electrophoresis at pH 6.5. After acid hydrolysis, the amino acid composition showed appropriate molar ratios. Ubiquitin was isolated as described previously⁷. The dual induction assay for T-cell and B-cell differentiation in fractionated bone marrow cells from newly hatched chickens was carried out as described previously⁸. Synthetic FTS induced both T-cell and B-cell differentiation (Fig. 1) with high dose inhibition at the higher concentrations ($100 \mu\text{g ml}^{-1}$). B-cell induction was only obtained consistently at a concentration of $1 \mu\text{g ml}^{-1}$, whereas T-cell induction was obtained over the broader concentration range of 1 ng ml^{-1} to $1 \mu\text{g ml}^{-1}$. More detailed information about the mechanism of induction by FTS was obtained from inhibition studies, the inhibiting agent being added at the same time as the inducing agent (Table 1). Inductive concentrations of FTS ($1 \mu\text{g ml}^{-1}$) were inhibited by inhibitory concentrations of ubiquitin ($100 \mu\text{g ml}^{-1}$), and inductive concentrations of ubiquitin ($0.5 \mu\text{g ml}^{-1}$) were inhibited by inhibitory concentrations of FTS ($100 \mu\text{g ml}^{-1}$). Inductive concentrations of both FTS and ubiquitin were inhibited by propranolol 10^{-5} M , which did not affect induction by cyclic AMP.

Fig. 1 Relationship between concentration of synthetic FTS and induction of Bu-1⁺ (a) or Th-1⁺ cells (b) in fractionated bone marrow from newly hatched chickens. Bone marrow cells from newly hatched chickens were fractionated by ultracentrifugation on a discontinuous bovine serum albumin gradient, and cells from the lighter layers were incubated with or without various concentrations of FTS. After incubation for 2.5 h, cells were washed and tested in the cytotoxicity assay using anti-Bu-1 and anti-Th-1 alloantisera and a mixed avian-mammalian complement system as described previously⁸. FTS induced both Bu-1⁺ and Th-1⁺ cells and showed high-dose inhibition (six experiments, each line represents one experiment).

Table 1 Inhibitor studies with synthetic FTS and ubiquitin in the dual induction assay using chicken cells

Inducing agent	Inhibiting agent	Cells induced (%)	
		B cells (Bu-1 ⁺)	T cells (Th-1 ⁺)
FTS 1 µg ml ⁻¹	—	11,16	11,19
FTS 1 µg ml ⁻¹	Ubiquitin 100 µg ml ⁻¹	1,0	2,0
—	Ubiquitin 100 µg ml ⁻¹	1,0	0,0
Ubiquitin 0.5 µg ml ⁻¹	—	9,16	20,16
Ubiquitin 0.5 µg ml ⁻¹	FTS 100 µg ml ⁻¹	0,0	0,0
—	FTS 100 µg ml ⁻¹	0,0	0,0
FTS 1 µg ml ⁻¹	—	15,22	18,20
FTS 1 µg ml ⁻¹	Propranolol 10 ⁻⁵ M	0,0	0,0
Ubiquitin 0.5 µg ml ⁻¹	—	19,11	15,17
Ubiquitin 0.5 µg ml ⁻¹	Propranolol 10 ⁻⁵ M	0,0	0,0
Cyclic AMP 0.2 × 10 ⁻³ M	—	18,8	21,17
Cyclic AMP 0.2 × 10 ⁻³ M	Propranolol 10 ⁻⁵ M	19,13	11,14

High concentrations of FTS or ubiquitin inhibited inductive concentrations of the other. Inductive concentrations of either were inhibited by propranolol.

Each figure represents the mean of duplicate or triplicate tubes in a single experiment.

The amino acid sequence of FTS (refs 1, 2) differs from that of thymopoietin^{10,11}, and the biological activity of these two peptides in the dual induction assay was also quite different. Bovine thymopoietin was inactive in the dual induction assay in the chicken⁸. Unlike bovine thymopoietin⁷, porcine FTS was both active and non-selective in the dual induction assay using chicken cells and was inhibited by propranolol. By contrast, our findings show a close similarity between the activity of FTS and that of ubiquitin, in that both caused non-selective induction in the dual induction assay; induction by both was inhibited by the β -adrenoceptor-blocking agent, propranolol; and in that high concentrations of each inhibited induction by inductive concentrations of the other. This finding is especially noteworthy because the primary structure of FTS does not closely resemble that of ubiquitin^{12,13}; the similarity of tertiary structure of the active sites implied by the similarities of activity of these two peptides must be generated by folding of chains of dissimilar primary amino acid sequence. Evolutionary convergence rather than modification of a common ancestral gene would be the likely cause of this relationship¹⁴.

We conclude that FTS is a biologically active molecule that induces lymphocyte differentiation, and that the biological activity of FTS mimics ubiquitin, a polypeptide which induces lymphocyte differentiation non-selectively by reason of having an adrenomimetic active site. Our observations indicate that FTS is probably not a thymic hormone, but they do confirm that this circulating non-peptide can induce lymphocyte differentiation. These findings do not detract from interest in this factor. Rather, they raise important questions concerning its origin in the body and a possible physiological role in regulating lymphocyte differentiation and maturation.

Expression of MuLV GP71-like antigen in normal mouse spleen cells induced by antigenic stimulation

ALL mouse strains investigated possess cellular DNA sequences which are homologous to the genomes of endogenous C-type particles¹. Also, major envelope glycoproteins of the oncoviruses², such as GP71, are found on the surface of normal cells and they display a considerable polymorphism. An antigen serologically indistinguishable from AKR murine leukaemia virus (MuLV) GP71 is present in normal bone marrow cells of all mouse strains investigated but not in normal spleen cells³. Allogeneic⁴ and mitogenic stimulation^{5,6} of spleen cells have been reported to result in C-type particle synthesis in some but not all mouse strains. We report here that both T and B lymphocytes of mice express a GP71-like antigen on their surfaces if antigenically stimulated.

Goat⁷ or rabbit⁸ antisera prepared against isolated GP71 of Friend leukaemia virus (FLV) were applied to the mouse lymphocytes. In some experiments, a goat antiserum prepared against dissociated feline leukaemia viruses (FeLV) was included⁹. These antisera possess antibodies to type-, group- and interspecies-specific determinants of MuLV GP71 (ref. 10) and thus can react with the major glycoprotein moieties of all C-type murine oncoviruses. The antisera and the normal control sera were thoroughly absorbed with fresh suspension of liver and spleen cells of the mouse strains used in a particular experiment. Fresh rabbit sera served as source of complement. Mishell–Dutton-type cultures of mouse spleen cells activated by sheep red blood cells (SRBC) were used to examine the effect of anti-GP71 antisera on the primary immune response *in vitro*¹¹. The immune responses were assessed by the haemolytic plaque test of Jerne¹² as modified by Mishell and Dutton¹¹. The number of plaque-forming cells (PFC) routinely increases after 3 d of culture and usually reaches an optimum on day 5.

Table 1 shows that the addition of anti-GP71 antiserum to spleen cultures of F₁ hybrid mice (C57B1/6 × DBA/2 = B₆D₂) on day 3 of culture significantly reduced the number of PFC

discovered on day 5 dependent on the presence of active complement. Since the anti-SRBC response is T-cell dependent¹³, either T or B lymphocytes or both may be affected by the treatment. To determine whether or not antibody-producing B cells can thus be affected, cultured cells were treated directly before the plaque assay when all of the antibody-producing B cells were already present.

While the controls treated with normal goat serum (NGS) and complement (C) contained 4,147 PFC per 10^6 recovered cells, treatment with anti-FLV GP71 antiserum and C resulted in a drastic reduction (125 PFC per 10^6 cells = 3%). Plaque-forming cells were similarly reduced by treatment with anti-FeLV antiserum and complement (65 PFC per 10^6 cells = 1.6%). This suggests that the induced antigen is in fact viral GP71 and not simply another membrane structure displaying a chance cross-reactivity. Anti FLV GP71 antiserum reacts predominantly through group-specific determinants on the GP71 molecules of all mouse oncoviruses while anti-FeLV antiserum can only detect their interspecies-specific determinants. Thus, antibody-producing B lymphocytes of $B_6D_2F_1$ mice express sufficient GP71-like antigens on their surface to be eliminated by corresponding antisera and complement.

Examination of a plaque centre cell revealed actual C-type particle synthesis by these antibody-producing cells. Immunological induction of GP71-like viral antigens is, however, also possible in lymphocytes of NIH-Swiss mice. These mice only possess a xenotropic provirus¹⁴.

The following experiments were designed to find out whether or not T-helper cells also express oncoviral antigens on immunological stimulation. For this purpose, C57B1/6 mice were primed and boosted with dinitrophenyl (DNP)-KLH *in vitro* using the method of North and Askonas¹⁵. In secondary spleen cultures derived from those mice and restimulated with DNP-KLH, a considerable IgG immune response is obtained (Table 2). The removal of T-helper cells by treatment with anti-Thy 1 and complement before the culture prevents the immune response which, however, can be reconstituted by addition of specifically antigen-activated T cells¹⁶ (Table 2). These reconstituting T-helper cells, however, are sensitive to anti-FLV GP71 antiserum and complement, indicating that, like immunologically activated B lymphocytes, they also express the GP71-like antigen. This is of particular interest since concanavalin A stimulation of C57B1/6 spleen cells leads to the induced expression of GP71-like antigens without C-type particles synthesis in contrast to DBA/2J or $B_6D_2F_1$ cultures where both occurs (manuscript in preparation).

Our results suggest that both T and B lymphocytes of mice, if antigenically stimulated, either *in vivo* or *in vitro*, display GP71-like antigens on their surfaces where they are accessible to antibodies.

To demonstrate more directly that unstimulated lymphocytes do not express these antigens, the following experiment was performed. Spleen cells of mice primed and boosted with DNP-KLH were treated with normal goat or with goat anti-FLV GP71 antisera and complement before culture. One set of cultures

Table 2 Effect of anti-FLV GP71 antiserum and complement on primed spleen cells of C57B1/6 mice

Treatment before culture	PFC per 10^6 cells (anti-DNP IgG) day 5	% Control
None (control)	4,716	100
T-helpers reduced (TR)	245	5
TR + untreated helpers	4,820	102
TR + treated helpers (NGS + C')	2,498	53
TR + treated helpers (GP71 + C')	789	16
